Adolescent and adult malignant TGCTs are universally aneuploid, and polyploidization of germ cells has been emphasized as an early event in testicular germ-cell tumorigenesis.[306,307] IGCNU and seminoma cells are hypertriploid, whereas nonseminomas of all histologic types are hypotriploid. TGCTs consistently exhibit biallelic expression of imprinted genes.[102,308-312] Erasure of parental imprinting occurs in mammalian embryonic germ cells,[313,314] implying the origin of TGCTs from an early germline cell.[1]

The most common cytogenetic aberrations in TGCTs are relative loss of all or parts of chromosomes 4, 5, 11, 13, 18, and Y and gain of material from chromosomes 7, 8, 12, and X.[307,315-321] Of these, the most consistent chromosomal aberration in adolescent/adult malignant GCTs is the overrepresentation of chromosome 12p, which is found in all histologic subtypes and primary sites (ovarian, testicular, and extragonadal).[322-331] A characteristic isochromosome 12p (i[12p]) can be detected cytogenetically in 80% of cases;[59] in other cases, an increased copy number of 12p sequences can be detected on derivative chromosomes.[332] Along with tumor markers such as β-HCG, the detection of i(12p) can identify a germ-cell origin in cases of carcinoma of unknown primary.[333] Further analysis has identified a particular amplicon, 12p11-12p12.1, that is present in many TGCTs.[334,335] Candidate genes in the 12p region include the oncogenes *KRAS* and *CCND2*, as well as the stem cell–specific genes *NANOG* and *STELLAR/DPPA3*; however, the precise contribution of 12p amplification to the pathogenesis of GCTs remains unclear.[*] 12p amplification appears to be a late event in GCT pathogenesis, because it is not present in the precursor lesion, IGCNU.[342]

Molecular genetic analysis of teratomas further supports the hypothesis of different histogenetic origins of different types of teratomas.[133] The malignant teratoma component of mixed ovarian or TGCTs uniformly exhibits the same genomic aberrations as the other malignant components of the tumor, including i(12)p. In contrast, mature, cystic ovarian teratomas and dermoid and epidermoid cysts of the testis exhibit normal karyotypes.[†] Based on these observations, Ulbright has proposed that mature ovarian teratomas develop directly from transformed germ cells, whereas the post-pubertal testicular teratomas develop through a malignant IGCNU stage, as do the other malignant post-pubertal TGCTs.[133]

A recent study of genome-wide copy number variation (CNV) in seminomas using high-resolution single-nucleotide polymorphism (SNP) arrays confirmed many of these reported findings and identified novel CNVs, including both amplifications and homozygous deletions.[344] Several genes identified in regions of recurrent CNV are potential candidate seminoma susceptibility genes, including *FAT3, EDNRB1*, and *RASSF8*.

Genomic aberrations seen in MGCTs of infants and children are generally distinct from those occurring in postpubertal tumors.[19,60,154,202,303] Pediatric GCTs show only partial erasure of parental imprinting, indicating that prepubertal GCTs likely arise from an earlier stage of embryonic germ cell development than do the postpubertal tumors.[‡] A similar pattern of imprinting is seen in gonadal and extragonadal pediatric GCTs, suggesting that gonadal and nongonadal tumors share a common pathogenesis and cell of origin.[100,102,154,305,346]

In analyses of chromosomal structure and copy number imbalances, differences between the pediatric and adolescent/adult GCTs are again consistently found. In the prepubertal period, pure teratomas of the testis or of extragonadal sites nearly always exhibit a normal profile in genomic analyses, including classical cytogenetics, fluorescence in situ hybridization, loss-of-heterozygosity analysis, and array CGH.[§] These data contrast sharply with the universally abnormal cytogenetic profile of postpubertal teratomas arising as a component of a mixed malignant GCT. In adolescents and adult GCTs, only mature teratomas of the ovary and dermoid and epidermoid cysts of the testis exhibit normal cytogenetics, suggesting that these tumors may share a common pathogenesis with the prepubertal teratomas.[123,133]

In children under the age of 5 years, YST is the most common malignant GCT of the testis and of extragonadal sites. Unlike teratomas, cytogenetic and other genomic aberrations are consistently reported in analyses of YSTs in infants and children. The most common imbalances reported are gains at chromosomes 1q and 20q and losses at chromosome 1p and chromosome 6q.[¶] More recently, the advent of higher-resolution techniques such as array-based CGH has further defined chromosomal aberrations in this group of tumors. Veltman et al[203] reported the array CGH profiles of a series of 24 GCTs from patients aged younger than 5 years, including 16 teratomas and eight YSTs. Most of the teratomas had normal CGH profiles, with two teratomas exhibiting loss of chromosome 20p as the only recurrent change. In contrast, all of the YSTs had abnormal profiles. The recurrent changes, seen in at least three of the eight YSTs, included gains of chromosomes 1q (1q32-1qter), 3p (3p21-pter), and 20q (20q13) and loss of chromosomes 1p (1p35-pter), 6q (6q24-qter), and 18q (18q21-qter). In the Veltman et al study, only one tumor from a child aged younger than 5 years exhibited gain of chromosome 12p, whereas five of seven cases from children older than 5 years showed gains at chromosome 12 p. Most of these tumors occurred in the ovary, supporting the hypothesis that ovarian and testicular MGCTs have a common pathogenesis, at least in older children and adults.[1,353] Another study from the U.K. Children's Cancer and Leukaemia Group examined the metaphase CGH profile of 34 malignant GCTs in children aged younger than 16 years.[354] This study supported the previous reports of an increased frequency of loss of chromosomes 1p and 6q and gain of chromosome 3p in YSTs. Intriguingly, 4 of 14 MGCTs from children younger than 5 years of age demonstrated gain of 12p, including in two cases gain of the 12p11 locus that is strongly associated with adolescent and adult MGCTs. Therefore childhood and adolescent/adult MGCTs may share more pathogenic mechanisms in common than has been previously appreciated based on the analysis of a relatively small number of cases.

Loss of chromosomes 1p and 6q correlates with loss-of-heterozygosity analysis indicating true allelic loss in these regions in pediatric GCTs.[349,355] However, the most common chromosomal aberrations of pediatric GCTs 1p–, 1q+, 6q–, and 20q+ are not highly specific for GCTs but are seen in other cancers of childhood, including neuroblastoma and Wilms tumor, as well as carcinomas.[356,357] Deletion of chromosome 1p is associated with *MYCN* amplification and poor prognosis in neuroblastoma,[358,359] which has led to the speculation that one or more genes in this interval may act as a tumor-suppressor in neuroblastoma.[360] Several candidate genes have been proposed, including *CHD5, TNFRSF25, CAMTA1,* and

AJAP1.[361] *CHD5* was shown to act as a tumor-suppressor in vivo.[70] Whether these or other genes in the 1p and 6q deleted regions play a pathogenic role in pediatric MGCTs is not known.

Genome-Wide Association Studies

A number of genome-wide studies have used SNP arrays to analyze the constitutional (germline) DNA of men with TGCT, resulting in the identification of a large number of novel GCT susceptibility loci. In 2009 two groups reported strong linkage of GCT susceptibility to loci on chromosomes 5, 6, and 12, suggesting roles for *SPRY4* and *KITLG*, both components of receptor tyrosine kinase signaling, as well as for the proapoptotic *BAK1* gene.[362,363] A follow-up study by Turnbull and co-workers identified additional susceptibility loci near the *DMRT1*, *TERT,* and *ATF7IP* genes.[364] The studies have subsequently been replicated in other patient populations.[365-367] More recently, further GWAS studies have identified new candidate GCT susceptibility loci, including genes with potential roles in telomere regulation, such as *PITX1*, or germ-cell development, such as *TEX14, RAD51C, PRDM14,* and *DAZL*.[368,369]

The Role of Developmental Signaling Pathways in Germ Cell Tumor Pathogenesis

Compared with many other solid malignancies, relatively few somatic mutations have been described in GCTs. The most commonly reported mutated gene is *KIT*, a tyrosine kinase growth factor receptor that plays important roles in germ cell development.[199,243,370-373] Mutations have also been reported in *NRAS* and *KRAS*, signaling components of the mitogen-activated protein (MAP) kinase pathway that act downstream of *KIT*.[374-377] Interestingly, somatic mutations in *BRAF*, another MAP kinase pathway member, have been associated with cisplatin resistance in adult TGCTs[378]; however, *BRAF* mutations appear to be rare in pediatric GCTs.[379]

Large-scale genomic profiling projects, now underway in several centers, will be required to fully delineate the mutational landscape of MGCTs. Other mechanisms impairing normal gene expression in GCTs such as CNV and aberrant miR expression are being explored (described previously), as is differential methylation. Epigenetic modulation of gene expression through promoter DNA methylation is commonly found in adult and pediatric GCTs. Smiraglia and co-workers first reported that seminomas are globally hypomethylated compared to nonseminomas,[380] whereas Netto et al. extended these observations to show that IGCNU cells, like seminomas, appear globally hypomethylated. Other groups have examined the potential contributions of differential methylation to TGCT susceptibility[381] or cisplatin resistance.[382] Two recent studies examined global DNA methylation patterns specifically in pediatric GCTs. Jeyapalan and co-workers found that pediatric YSTs exhibited a "methylator" phenotype, perhaps attributable to higher expression of DNA methyltransferase 3B in these tumors. Among the genes predicted to be silenced were several associated with caspase-8–dependent apoptosis.[383] Amatruda et al. found a similar pattern of differential methylation comparing YSTs to seminomas and further identified effects on the expression of genes associated with stem cell pluripotency and Wnt/β-catenin signaling.[384]

In addition to these efforts, many studies have focused on understanding how aberrant control of normal developmental pathways may play a role in GCT pathogenesis. Fritsch and co-workers showed that pediatric YSTs and teratomas express active Wnt/β-catenin signaling and Wnt target gene expression.[385] Pediatric YSTs express high levels of *BMP2*, a component of the BMP signaling pathway,[291] and expression of *BMP7* is associated with poor outcome in TGCTs.[293] The importance of BMP was further revealed in the analysis of zebrafish bearing inactivating mutations in a cell-surface BMP receptor, which develop GCTs strongly resembling human seminomas.[386] Thus the state of BMP signaling distinguishes undifferentiated tumors such as seminomas from the more differentiated nonseminomas.[387]

Another key developmental pathway concerns the pluripotency gene *LIN28*, which is universally expressed in GCTs.[388-390] Whereas *LIN28* expression is critical for normal embryonic development, prolonged or aberrant *LIN28* expression in germ cells may be pathogenic, owing to *LIN28*'s ability to block maturation of the let-7 family of tumor-suppressing miRs.[390] Let-7 normally regulates a number of genes associated with proliferation such as *MYCN*, *RAS*, *AURKB,* and *CCNF*, and Murray et al. have shown that *LIN28* expression drives the upregulation of many of these oncogenes in GCT cells.[391]

Although the above studies have begun to yield important insight into the mechanisms by which perturbations in the Wnt, BMP and *LIN28*/let-7 pathways may contribute to GCT pathogenesis, strategies to target these defects are still at fairly early stages of development. There may potentially be more immediate translational impact from the finding that GCTs express cell-surface proteins that have been successfully targeted by monoclonal antibodies in other solid tumors, including *ERBB2/Her-2*, *CD30*, and epithelial cell adhesion molecule (EpCAM).[392-396]

DIAGNOSIS AND STAGING OF PEDIATRIC GERM CELL TUMORS

In this section, the clinical presentation of GCTs, evaluation of the patient for metastatic disease, and the use and interpretation of the tumor markers in the diagnosis and staging of GCTs will be discussed. The surgical approach, for purpose of both diagnosis and staging, will also be delineated.

Clinical Presentation of Pediatric Germ Cell Tumors

The clinical presentation of a pediatric GCT is determined by the site of origin. Site of origin varies by age. Gonadal tumors, particularly testicular tumors, do present during infancy but are more common after the onset of puberty. The site of the extragonadal GCT also varies as a function of age at diagnosis. Sacrococcygeal tumors, much more common in females than males, present either at birth (typically mature/immature teratomas) or between 6 months and 4 years of life (typically

MGCT with a large component of YST). Mediastinal tumors are rare in infancy; incidence begins to rise at onset of puberty, particularly among males. Site-specific features of the presentation are discussed in the sections that follow.

Presentation of Testicular Germ Cell Tumors

Testicular GCTs most often present with painless generalized swelling of the scrotum. Gynecomastia and infertility are rarely present,[220] though subfertile and infertile men do appear to have an increased risk of developing TGCT.[397,398] Local extension to the spermatic cord and the epididymis may occur, and the presenting symptoms can be mistaken for epididymitis. Symptoms of metastasis, including back or abdominal pain, cough or dyspnea, are present at diagnosis in about 10% of adult patients.[69]

An initial testicular ultrasound that shows the lesion to be intratesticular with areas of microcalcification is often helpful in clarifying the differential diagnosis, which includes lymphoma and paratesticular rhabdomyosarcoma. Eighty-five percent of children younger than age 4 have a tumor that is confined to the testes (stage I), as compared with only 35% of adults.[399]

Choriocarcinoma is the most aggressive histologic subtype of testicular GCT, with a propensity to hematogenous metastasis. Patients may have an occult primary tumor and few or no testicular complaints but rather symptoms caused by hemorrhage of visceral metastases, such as hemoptysis or neurologic symptoms resulting from brain metastases. Because of the risk of hemorrhage, the suspected diagnosis of metastatic choriocarcinoma is a medical emergency that requires prompt initiation of treatment, often without confirmatory biopsy and just on the presumption of the diagnosis given the presenting signs, symptoms, radiologic appearance, and markedly elevated β-HCG. However, it has been hypothesized that chemotherapy may actually precipitate hemorrhage, and therefore patients need very careful monitoring; some have advocated initiation of chemotherapy in an intensive care–unit (ICU) setting. With the extreme elevation of the serum β-HCG that can be seen in choriocarcinoma, occasional patients manifest thyrotoxicosis or gynecomastia resulting from the cross-reactivity of β-HCG with the thyroid and luteinizing hormone receptors.[220,400-404]

Presentation of Ovarian Germ Cell Tumors

Ovarian GCTs typically present with abdominal pain and a palpable pelvic-abdominal mass (85%).[405] Symptoms of acute abdomen occur in about 10% to 25% of patients and are usually caused by rupture, hemorrhage, or torsion of the ovarian tumor that requires immediate surgical exploration.[258] Other less common presenting symptoms include abdominal distension (35%), fever (10%), and vaginal bleeding (10%). Rarely, patients can experience precocious puberty resulting from the production of β-HCG by the tumor. Not uncommonly, a young girl with an abdominal/pelvic mass and and an elevated β-HCG is assumed to be pregnant. This assumption is especially distressing for young females who are peripubertal and have not yet have initiated sexual intercourse.

If the diagnosis of dysgerminoma is made, it is important to recognize that 10% to 15% of cases are bilateral; therefore the finding of dysgerminoma on frozen section during surgical exploration of an ovarian mass generally warrants close inspection and sometimes biopsy of the contralateral ovary.[406-409] Most dysgerminomas present as stage I (disease confined to the ovary),[406-409] but lymphatic metastasis of these tumors to pelvic, paraaortic, mediastinal, and supraclavicular lymph nodes can occur.[216,410,411] Five percent of dysgerminomas arise in dysgenetic gonads of girls with 46XY (Sweyer syndrome or testicular feminization) or who have 45X/46XY mosaicism.[412] For this reason, karyotyping should be considered for all girls with a prepubertal pelvic mass.[216] If dysgenetic gonads and/or the presence of Y-chromosome material are detected, removal of both of the gonads is indicated because of the 25% to 50% risk of developing malignancy such as a gonadoblastoma or dysgerminoma in the contralateral ovary.[66,110,413,414] See "Epidemiology of Pediatric Germ Cell Tumors" for more information.

Presentation of Sacrococcygeal Germ Cell Tumor

Sacrococcygeal teratomas (SCTs) occur predominately in females. In Altman's classic 1974 review of 405 clinical cases, 74% occurred in females.[415] However, even though SCTs are much more common in females, rate of malignancy does not vary by gender. Of note, 18% of patients with SCT had associated congenital anomalies. The most prevalent defects were in the musculoskeletal system, but other organ systems that were involved included renal, cardiovascular, gastrointestinal, and central nervous systems. More than half of the patients were diagnosed on the first day of life, but approximately 10% were diagnosed after 1 year of age.

Altman classified sacrococcygeal tumors by the degree of internalization vs. externalization of the tumor (Fig. 63-13).[415] An "Altman type I" SCT is a tumor that is entirely external; an Altman type IV SCT is entirely internal. Altman was the first to note the correlation between rate of malignancy, age at diagnosis, and degree of internalization. At younger than 2 months of age, 7% of girls and 10% of boys had malignant tumors, whereas after 2 months of age, more than half of the tumors were malignant (48% of SCT in girls and 67% of SCT in boys).[415]

Most neonatal SCTs have a significant external component (Altman type I or II) and can be completely excised in the neonatal period. Over 90% are benign lesions (either mature or immature teratoma) that do not require further therapy. Recurrence rates after resection of neonatal mature or immature teratoma have been estimated to range from 4% to 21% with a malignancy rate of 50% to 70%.[192,416] The reason that a fraction of neonatal tumors do recur could either be because of oversight of a malignant element during the initial pathologic review, such as a microscopic foci of YST, or because malignant transformation of a small benign remnant left in situ after the initial procedure. Presacral tumors that are predominately internal present later in infancy through age 4 years. Usual presenting symptoms of an internal lesion are either constipation or a buttock/abdominal mass; probability is quite high that these lesions are malignant.

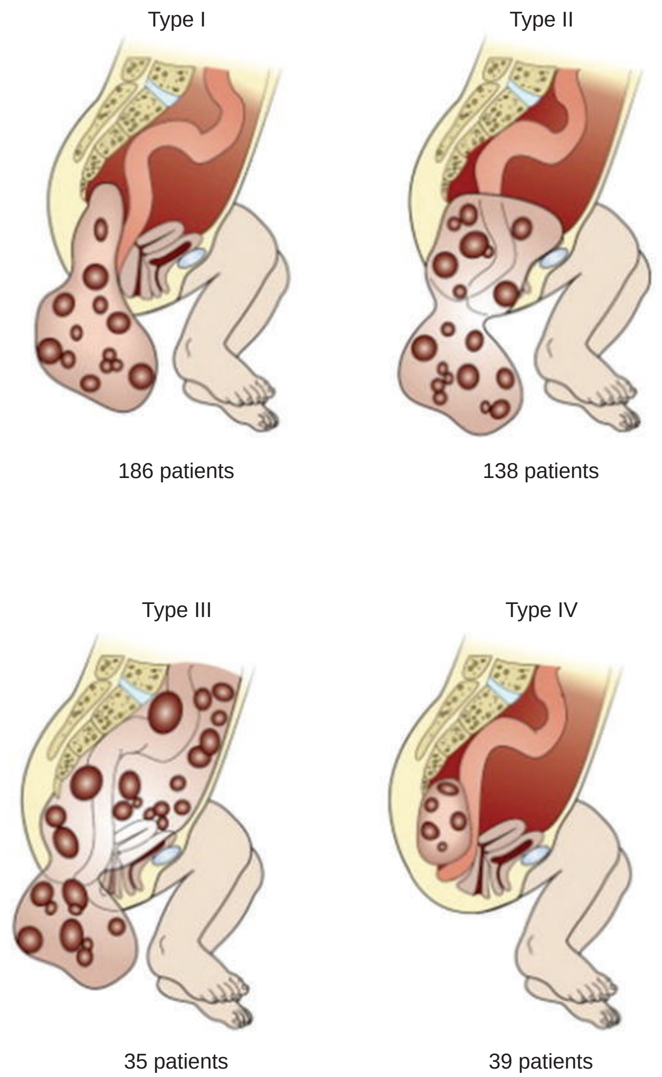

Figure 63-13 Altman classification of sacrococcygeal germ cell tumors. SCTs are classified according to their degree of internalization. Type I tumors are nearly entirely external; in type II tumors the mass extends equivalently into and external to the pelvis. Type II tumors have only minimal external component, and Type IV tumors are entirely internalized. The numbers of patients with each type of tumor in this series of 398 patients is shown. *(From Altman RP, Randolph JG, Lilly JR: Sacrococcygeal teratoma: American Academy of Pediatrics Surgical Section Survey, 1973.* J Pediatr Surg *9:389–398, 1974.)*

Presentation of Mediastinal Germ Cell Tumors

In a series of patients with mediastinal GCTs registered on the German MAKEI protocols, chest pain or respiratory symptoms such as cough or dyspnea were the most common presenting clinical symptoms.[417] Other presenting clinical scenarios included discovery of the mass as an incidental finding on fetal ultrasound or during a workup for pneumonia that did not resolve with standard antibiotics. In the MAKEI experience, all mediastinal tumors that presented at younger than 1 year of age (n = 9) were either mature or immature teratomas.[417] Mediastinal tumors presenting after infancy but before puberty were either pure YSTs or had predominant yolk sac components. Embryonal carcinoma was more prevalent after the age of 10 years. Mediastinal seminoma was not diagnosed before age 10 years.

Presentation of Extragonadal Germ Cell Tumor at Other Sites

Extragonadal GCTs are the most common fetal and neonatal neoplasm; perinatal teratomas present at wide array of sites. In a review of all perinatal GCTs reported in the literature from 1965 through 2004, the author identified 534 cases.[56] The sacrococcygeal site is the most common (40%), but perinatal GCTs have also been reported in the cervical area (30%), in the oropharynx and nasopharynx (8%), and in other sites including cardiac (7.5%), gastric (2.6%), orbital (2.4%), facial (1.5%), mediastinal (2.6%), and placental (1.5%) locations. In addition, there were 17 teratomas reported in other sites, including tongue, tonsil, liver, retroperitoneum, ileum, mesentery, vulva, and the anorectal area. In addition, 25 cases of fetus in fetu were reported. Most common reasons for diagnosis included detection of a mass on prenatal ultrasound, polyhydramnios, or respiratory distress. Other symptoms were specific to site; for instance, pericardial effusion and tamponade were the most common signs in neonates with intracardiac teratomas. The vast majority of perinatal GCTs are benign, either mature or immature teratomas. Overall the incidence of YST within the neonatal teratoma was 5.8%; the highest rate of YST (10%) was documented in SCTs. Teratomas detected antenatally had three times the mortality rates as those diagnosed postnatally. Fetal survival rate was 53%; neonatal survival rate was 85%. Cause of death was most commonly either because of prematurity or to hydrops. Survival rate was only 7% among those patients whose tumors were diagnosed as a result of fetal distress before 30 weeks of gestation.

Evaluation for Metastatic Disease

The current system for staging pediatric GCTs in use by the COG is shown in Table 63-3.[418] All patients suspected of having a GCT should have a radiologic evaluation of the extent of the disease including either an ultrasound (if testes is the primary site), computed tomography (CT), or magnetic resonance imaging (MRI) of the primary site; abdominal/pelvic CT if the tumor is likely to drain to the lymph nodes of the retroperitoneum and abdomen; and a chest CT. Radiologic staging is preferably obtained preoperatively so that the clinician does not have to differentiate between malignant involvement and postoperative changes (i.e., atelectasis on the chest CT or postoperative lymph node enlargement after surgery). GCTs can also metastasize to brain and bone. Although bone and brain metastases are generally considered quite rare, German investigators reported that up to 10% of patients have bone metastasis, and that incidence was as high as 26% among stage IV patients.[419] On the last combined U.S. intergroup GCT study, 6% of patients overall had bone metastases, but the incidence increased among stage IV patients, of whom 13% had bone metastases at diagnosis.[420] Brain metastases are present in about 4% of adults with GCT. In a review of the St. Jude experience in 206 cases of pediatric GCT from 1962 to 2002, 16 patients in the series had brain metastases at some point

TABLE 63-3 Staging of Testicular, Ovarian, and Extragonadal Tumors

Testicular	
I	Limited to testis, completely resected by high inguinal orchiectomy; no clinical, radiographic or histologic evidence of disease beyond the testis; tumor markers normal after appropriate half-life decline: patients with normal or unknown markers at diagnosis must have negative ipsilateral retroperitoneal lymph node sampling to confirm stage I disease.
II	Transscrotal orchiectomy; microscopic disease in scrotum or high in spermatic cord (<5 cm from proximal end): retroperitoneal lymph node involvement (<2 cm) and/or increased tumor markers after appropriate half-life decline
III	Tumor-positive retroperitoneal lymph node(s) >2 cm diameter: no visceral or extra abdominal involvement
IV	Distant metastases that may include liver
Ovarian	
I	Limited to ovary, peritoneal washings negative for malignant cells; no clinical, radiologic, or histologic evidence of disease beyond the ovaries (gliomatosis peritonei did not result in upstaging): tumor markers negative after appropriate half-life decline
II	Microscopic residual or positive lymph nodes (<2 cm); peritoneal washings negative for malignant cells (gliomatosis peritonei did not result in upstaging); tumor markers positive or negative
III	Gross residual or biopsy only; tumor-positive lymph node(s) >2 cm diameter; contiguous visceral involvement (omentum, intestine, bladder); peritoneal washings positive for malignant cells
IV	Distant metastases that may include liver
Extragonadal	
I	Complete resection at any site; coccygectomy included as management for sacrococcygeal site; negative tumor margins
II	Microscopic residual; lymph nodes negative
III	Gross residual or biopsy only; regional lymph nodes negative or positive
IV	Distant metastases that may include liver

during treatment.[421] Only two patients (1%) had brain metastases at diagnosis. Twelve patients were diagnosed at relapse, and 2 patients were discovered to have brain metastases at autopsy. Most patients with brain metastases had clinical symptoms (12/16) and also had concurrent pulmonary metastases (14/16). The data may overestimate the incidence of brain metastases, however, because 11/16 were diagnosed before 1982 when cisplatin-based chemotherapy was not routine. Risk factors for the development of brain metastases in the St. Jude's study included extragonadal site (P = .013), advanced stage (P = .02) and choriocarcinoma (P < .001). In comparison, in a more recent cohort of the patients treated from 1990 through 1996 in the U.S. pediatric intergroup study, only three out of 299 patients were diagnosed with brain metastases; two of these patients were stage IV at diagnosis.[420] All patients had other sites of metastatic disease; the histology of all three patients included choriocarcinoma. Two of three patients are alive and well; one was treated with PEB alone and one patient received bleomycin, etoposide, and cisplatin (PEB) plus x-ray therapy (XRT). Therefore a bone scan should be obtained in all patients with advanced stage disease (stage III or IV), but head CT or brain MRI are recommended only for patients with stage IV disease, particularly in patients who have choriocarcinoma.

The use of fluorodeoxyglucose F 18 positron emission tomography (PET) has not been systematically evaluated in pediatrics, but its use is becoming more routine among adult patients with GCTs in the setting of a residual mass postchemotherapy. In a German study that compared the sensitivity and specificity of three different modalities for the evaluation of the residual mass, PET vs. CT vs. tumor markers, the results were as follows: PET, 59% sensitivity and 92% specificity; CT, 55% sensitivity and 86% specificity; and tumor markers, 42% sensitivity and 100% specificity.[422] The positive and negative predictive values for PET were 91% and 62%, respectively. Teratomas are not PET-avid. The authors concluded that PET did not add to the preoperative inference in the setting of a mass in which viable tumor was suspected by CT and tumor marker, but it was a useful adjunct in the setting in which tumor markers had normalized or the patient had marker-negative disease at diagnosis. PET-negative masses also require resection because of the possibility of residual teratoma that is PET-negative.

Tumor Markers

Specific subtypes of GCTs secrete proteins that can be used as markers of tumor presence. The pattern of these tumor markers and degree of elevation provide an indication of the likely histology (Table 63-4).[423] AFP is a glycoprotein that is synthesized by the fetal liver and yolk sac. AFP is elevated in patients with YST,[199] although low levels of AFP (generally <100 IU) are often observed in immature teratoma (perhaps because of occult microscopic foci of YST within the tumor). When an elevated AFP level is detected, one must consider other reasons for an elevated AFP in the differential diagnosis, including synthesis by a liver tumor, such as a hepatoma

TABLE 63-4 Histologic Subtype and Tumor Marker Levels

Term	Synonym	Comments*	Incidence Pre- vs. Post-Puberty	Tumor Marker
Seminoma	Dysgerminoma, germinoma	Seminoma-testes tumor; dysgerminoma-ovarian tumors; germinoma-extragonadal tumors	Post	Low levels of AFP; low levels of β-HCG in dysgerminoma caused by presence of multinucleated syncytiotrophoblastic giant cells
Endodermal Sinus Tumor	Yolk sac tumor	Most common form before puberty, besides teratoma	Pre	AFP +++
Embryonal Carcinoma			Post	AFP + β-HCG +++
Choriocarcinoma		Pure forms rare; most commonly one component of mixed GCT	Post	β-HCG +
Teratoma			Pre and Post	
Immature Teratoma			Pre and Post	≈⅓ of immature teratoma produce low levels of AFP
Dermoid cyst				
Polyembryoma				AFP +; β-HCG +
Mixed GCT		Tumors with more than one component are categorized by the most malignant component, not by the most common component	Pre and Post	Depends on the components

AFP, α-Fetoprotein; *GCT,* germ cell tumor; *HCG,* human chorionic gonadotropin.

*Much of the therapy for pediatric GCTs has been gleaned from experience treating testicular GCTs in adult males. An excellent guide for the workup and treatment of adult testicular tumors is the National Comprehensive Cancer Network (NCCN) Practice Guidelines in Oncology (http://www.nccn.org/).

or hepatoblastoma, or other disease states such as hypothyroidism, folate deficiencies, autoimmune disorders, acquired immunodeficiency syndrome (AIDS), congenital heart defects, cystic fibrosis, and platelet aggregation disorders. β-HCG is a peptide hormone produced in pregnancy, that is made by the embryo soon after conception and later by the syncytiotrophoblast (part of the placenta). Its role is to prevent the disintegration of the corpus luteum of the ovary and thereby maintain progesterone production that is critical for a pregnancy in humans. In tumors that originate in extraembryonic tissues, like choriocarcinoma, β-HCG can be significantly elevated. β-HCG is also sometimes mildly elevated in seminoma/dysgerminoma (<50 IU/L).

Interpretation of AFP levels must incorporate knowledge of age-related norms (see Fig. 63-6).[191,192] AFP is elevated in all infants at birth because there of continued synthesis of AFP by the fetal liver. Over the course of the first 2 years of life, AFP declines in normal infants as the synthesis in the liver ceases. To establish normal values for infants, Blohm et al analyzed data on 414 full-term infants, 90 preterm infants, and 259 children up to age 2 years from the University Hospital Düsseldorf (Germany).[192] Using regression analysis, the authors estimated that the half-life of AFP increases with age over the first 2 years of life. From birth to day 28, the half-life is estimated to be 5.1 days. The half-life of AFP increases thereafter to 14 days at 1 to 2 months of age, 28 days from 2 to 4 months of age, and 42 days from 4 to 6 months of age. The increase in the half-life of AFP with age also results in a "shouldering" of the AFP curve during the first 2 years of life. Not all children have adult levels of AFP by 2 years of age. In the Blohm study, the mean AFP at age 2 was 8 ng/mL; however, the 95% range extended between 0.8 and 87 ng/mL. Similar results were reported in an earlier and smaller study by Wu et al.[191] Values of AFP obtained in children under age 2 ought to be plotted on the nomogram developed by Blohm et al to determine whether the value falls within the normal range.[192]

Tumor markers may also be prognostic. In adult males with testicular cancer, the prognostic significance of postoperative tumors markers is well established. An international consortium pooled data on over 5000 men with testicular cancer and used multivariate analysis to investigate prognostic factors that created the International Germ Cell Consensus Classification (IGCCC), which divided patients into good, intermediate, and poor risk groups based on the extent of elevation of tumor markers, the presence of nonpulmonary visceral metastases or a nontesticular primary site of disease.[424] Although elevated tumor markers are one of the primary variables that determine risk group assignment in adult men, evaluation of the prognostic significance of tumor markers in pediatrics has been limited. In adult males, the failure of tumor markers to decline appropriately among poor-risk patients has also been shown to be a poor prognostic feature. Further discussion can be found in "Prognostic Factors at Diagnosis of Pediatric Germ Cell Tumors."

Tumor markers are also used prospectively to differentiate between stage I and II tumors. For patients with gonadal GCTs who have had all disease completely removed surgically and in whom no evidence of further disease is noted on pathologic or radiologic staging evaluations a watch-and-wait strategy is often recommended. However, if tumor markers fail to decline according to the expected half-life, the patient by definition has occult metastatic disease. The patient should be upstaged to stage II and therapy commenced.

There is one situation in which tumor markers may increase and not be cause for alarm. During the first cycle of chemotherapy, it has been observed that tumor markers can increase transiently. However, levels should have declined to the expected level by the start of the second cycle of chemotherapy.

SURGERY AND GERM CELL TUMOR

Surgery is an integral part of the management of GCTs. For benign tumors, complete excision is curative. For malignant tumors, proper staging and appropriate timing of excision are important for optimal outcome. At all sites, primary excision should be considered if the tumor can be safely removed without significant risk of morbidity. For tumors that pose risk to adjacent structures or expectation of incomplete excision, biopsy should be performed for diagnosis and neoadjuvant chemotherapy should be given. Reduction in tumor size allows greater expectation of safe and complete excision. Evidence is mounting that delayed resection of extragonadal tumors does not just decrease morbidity but also more importantly may increase survival, because of the ability to achieve complete resection at the time of the delayed surgery. In the case of expected malignancy, a child should be referred to a center with surgeons with experience in oncologic surgery, preferably a site that participates in COG clinical trials so that the proper staging can be done to allow for trial entry.

Surgical Approach to Sacrococcygeal Tumors

Over 90% of neonatal sacrococcygeal tumors are benign (mature or immature teratoma), and require complete excision at diagnosis should be attempted without harming adjacent structures. There is a 9% to 14% risk[425,426] of malignant recurrence in benign tumors, and long-term follow up care is important. Beyond the neonatal period, the risk of malignancy increases, and the tumor configuration is more likely to have an internal component (Altman types III and IV; see Fig. 63-13). Children with a large sacrococcygeal tumor suspected to be malignant should be evaluated for feasibility of resection. Gastrointestinal and genitourinary complications are far more common than lower extremity neurological sequelae, with up to 41% patients affected in one study.[39] Long-term follow up observation is mandatory in these children to ensure that normal bowel, bladder, and sensory-motor function is preserved.[40] If a problem is encountered, these children are best cared for by a multidisciplinary team that simultaneously initiates symptom management (such as management of constipation) with investigational studies including functional evaluations such as anorectal manometry and urodynamic studies (including direct electromyography [EMG] evaluation of the urinary sphincters) to define the extent of the problem at discovery as well as any progress (or lack thereof) in response to the prescribed interventions.[427] One final note is recognition of the recommendation by Ozkan and colleagues,[41] who suggest the need for defining the extent of neurologic, gastrointestinal, and genitourinary dysfunction before any intervention so as to better categorize any impairment of function at baseline and not just after surgery.[428] This suggestion is especially valuable for those patients whose tumors are discovered outside of the neonatal period.

Therefore an initial biopsy with a delayed resection must be seriously considered if morbidity is likely to be reduced.[429] In patients whose lesions involve the rectum or extend into the sacral bone or in patients already shown to have metastatic disease, biopsy rather than resection is the more appropriate initial surgical approach. If a needle biopsy is used to obtain diagnostic material, multiple passes should be obtained because of the histologic heterogeneity of these tumors and the possibility that the malignant foci will not be found in every sample. The histologic diagnosis should also be evaluated in the context of the information from tumor markers. A benign histologic diagnosis in the setting of elevated tumor markers should lead one to question whether there was a sampling error in the sample obtained or in the pathologic review. Lin28 is a new histochemical reagent that can be used to detect YST in the specific and sensitive way that should be used to detect occult YST.[388]

Delayed resection of a SCT has been definitively demonstrated not to adversely affect survival. In fact, German investigators have shown that patients with locally advanced and metastatic tumors actually had better overall survival when treated with chemotherapy before tumor resection. Overall survival for patients with delayed resection was 83%, whereas overall survival for patients who had an initial resection was only 45% ($P = 0.01$).[419] Preoperative chemotherapy allowed for more complete primary resection of the tumor; 19 of 31 patients had a complete resection after preoperative chemotherapy vs. only 11 of 35 patients who had a complete resection when definitive surgery was attempted before chemotherapy. Complete resection of the tumor, either at diagnosis or delayed until after chemotherapy, was the most significant predictor of event-free survival (EFS) in the German series of sacrococcygeal tumors (Fig. 63-14).[419] Second-look surgery was recommended for those with incomplete resection and had therapeutic benefit. Analysis of the data from the United States Pediatric Intergroup Trial (POG9049/CCG8882) also confirms that delayed resection did not have an adverse effect on prognosis.[416]

Most presacral lesions will be initially approached through a posterior transsacral incision. Superior

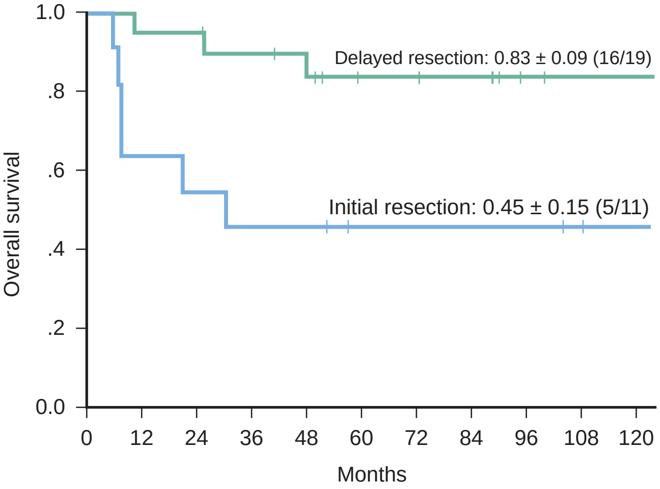

Figure 63-14 Five-year overall survival of 30 patients with locally advanced and metastatic malignant sacrococcygeal GCT (stage T2b M1) treated with initial resection versus delayed resection ($P = .01$, log-rank test). *(From Gobel U, Schneider DT, Calaminus G, et al: Multimodal treatment of malignant sacrococcygeal GCTs: a prospective analysis of 66 patients of the German cooperative protocols MAKEI 83/86 and 89.* J Clin Oncol *19:1943–1950, 2001.)*

extension of the tumor into the pelvis often requires a laparotomy. If laparotomy is performed, retroperitoneal lymph nodes should be examined and biopsied if enlarged. In all cases, the coccyx must be completely removed en bloc with the primary tumor. The importance of the resection of the coccyx was first noted by Gross, who reported a recurrence rate of 38% of those who had not had coccygectomy and 0% of those who had had a coccygectomy.[430]

Surgical Approach to Testes Tumors

Risk of malignancy is age dependent with 38% to 74% of testicular tumors in the prepubertal age group having benign histology.[121,122] In prepubertal boys with localized tumors, those with normal tumor markers and imaging studies can be considered for testis sparing enucleation of the tumor. Because the most common sites of metastasis of a testicular GCT are the retroperitoneal lymph nodes, a pelvic/abdominal CT scan should be obtained preoperatively. If the CT scan is delayed until after surgical exploration of the inguinal region, reactive retroperitoneal lymphadenopathy may be noted on CT scans and may be difficult to differentiate from metastatic disease. Evaluating the lungs for pulmonary metastases with chest CT before surgery is advisable, because postoperative atelectasis can make evaluation for malignant disease more difficult. Tumor markers should also be obtained preoperatively, because these levels are important to confirm the initial diagnosis and to provide prognostic information. In addition, the rate of decline is important to be able to track postoperatively in patients, especially in patients with stage I disease who are being expectantly observed, reserving chemotherapy only for those patients who have demonstration of residual malignant disease.

The surgical approach for a scrotal tumor should be through an inguinal incision. Control of the testicular vessels and vas deferens is gained at the level of the inguinal ring. The testis is then mobilized from the scrotum. Occasionally, a large testicular mass cannot be mobilized out of the scrotum into the inguinal region, and in this situation the inguinal incision should be enlarged to the superior aspect of the scrotum in order to avoid tumor rupture during mobilization. A radical orchiectomy is then performed with high ligation of all cord structures at the level of the internal inguinal ring. In prepubertal boys who have a focal lesion with normal markers and metastatic imaging, tumor enucleation protecting the tumor capsule followed by frozen section should be considered. If the frozen section is consistent with teratoma, the testis can then be placed back in the scrotal position, because enucleation is adequate therapy for prepubertal testicular teratoma. In the postpubertal boy, however, even localized teratoma has malignant potential and orchiectomy ought to be undertaken.

Rate of adherence to surgical guidelines was evaluated among the 63 patients with stage I GCT of the testes who were treated with observation only on the last U.S. intergroup trial from 1990 through 1996.[431] Adherence to guidelines could be verified in only 69% of the patients. Likelihood of adherence was directly related to whether or not the surgeon thought the diagnosis was tumor preoperatively. In patients in whom the preoperative diagnosis was malignant tumor, the surgical guidelines were followed in 80% of patients, whereas among patients in whom another preoperative diagnosis was suspected (i.e., hydrocele, hernia, torsion), the guidelines were followed in only 17%. There was no difference in recurrence rate among those patients in whom the surgical guidelines were followed and among those for whom the guidelines were not followed, with the exception of patients who had had scrotal violations. Among the four patients with transscrotal violation, three had recurrence of disease.

Based on detailed review of the surgical procedures followed in the CCG-POG Intergroup Study (INT0098), the surgical guidelines in the case of scrotal violation were revised. In cases in which a scrotal orchiectomy has been performed without violation of the tumor capsule, the patient may still remain in stage I. If the cord structures show evidence of tumor spread, the patient should be upstaged to stage II. However, if a scrotal biopsy was performed as the initial procedure, the scrotum is considered to be contaminated and the patient should be treated as having stage II disease. Hemiscrotectomy, however, is no longer required. In addition, a "completion orchiectomy" with removal of all cord structures to the level of the internal ring should be performed.

Evaluation of Retroperitoneal Nodes in Pediatric Testicular Germ Cell Tumors

Lymphatic drainage of the testes is to the retroperitoneal nodes and to the nodes below the renal vessels. Right testicular tumors usually metastasize to the nodes between the aorta and the inferior vena cava (interaortocaval nodes). Left testicular tumors metastasize to the nodes lateral to the aorta (paraaortic).[432] Left supraclavicular nodes and pulmonary nodules have been observed in the absence of retroperitoneal adenopathy. In adults, it is estimated that up to 30% of patients have false negative CT scans; in the most recent U.S. intergroup study of stage I testicular cancer among boys younger than 10 years of age, 5% of patients had failure of normalization of tumor markers postoperatively (i.e., patients had occult disease that was not detected on initial CT scan (false-negative initial CT scan). In total, 22% of patients presumed to be in stage I at diagnosis eventually relapsed, but all were salvaged with chemotherapy with 100% survival.[399]

If the preoperative CT scan of the abdomen has identified enlarged (≥4 cm) retroperitoneal lymph nodes, biopsy is not necessary, and one may assume that this represents metastatic disease; the patient should be treated as having stage III disease. If retroperitoneal lymph nodes are between 2 and 4 cm, a biopsy should be performed. If the retroperitoneal nodes are smaller than 2 cm, a biopsy is not required; however, the tumor markers (AFP and β-HCG) should be observed and return to normal with appropriate decline according the half-life (see previous discussion of tumor markers). In adult males, 10% to 20% of nodes between the size of 1 and 2 cm contain metastatic disease.

If the decision is made to biopsy a suspected node of the prepubertal boy, the retroperitoneal procedure should simply be a lymph node excision, not a full retroperitoneal lymph node dissection. If no biopsy is performed and the nodes are enlarged (>2 cm), that patient should be treated as a patient with stage III disease. But in adolescents (as in adults), if a biopsy is being undertaken to evaluate nodal disease, then a nerve-sparing modified template retroperitoneal lymph node dissection (RPLND) should be employed, which some surgeons would expand to a full bilateral nerve-sparing RPLND if any of the initial nodes are positive on frozen section. RPLND is both diagnostic and potentially therapeutic. For further discussion of RPLND please see the section on treatment of adolescent boys with stage I testicular cancer.

Metachronous Testicular Cancer

In adults, 3% to 5% of men with testicular cancer have a metachronous tumor in the other testicle at diagnosis, and 2% of men subsequently develop a tumor in the contralateral testicle. These risks have not been quantified for pediatric patients and no formal evaluation of the contralateral testis is recommended besides that continued thorough physical examinations, although a patient should be advised of the likely need for continued surveillance of the contralateral testis. Patients who have developed a testicular tumor in a cryptorchid testis are at increased risk of malignancy in the normally descended contralateral testes.

Surgical Approach to Ovarian Tumors

The largest series of ovarian GCTs (66 cases) estimated rate of malignancy in an ovarian mass as 19% at ages 0 to 5 years, 14% at ages 6 to 10 years, and 33% at ages 11 to 15 years.[258] AFP and β-HCG should be determined preoperatively for ovarian tumors. If not done preoperatively, these markers should be sent from the operating room once the diagnosis is apparent. The goals of the initial exploration for a suspected ovarian tumor are to completely resect the tumor if it can be accomplished without sacrifice of adjacent organs and to completely evaluate the extent of disease.

Surgical guidelines for ovarian GCTs were originally based on the experience with ovarian epithelial carcinoma, in which aggressive surgical resection is associated with higher chance of survival. Application of those surgical guidelines to ovarian GCTs, which have a different pattern of spread and are also highly chemosensitive, is not warranted. It is clear from studies in adult women with GCTs that fertility-sparing surgery (i.e., performing an unilateral instead of bilateral salpingo-oophorectomy) had no adverse outcome on survival.[238] On the most recently completed U.S. Intergroup Trial for gonadal tumors (CCG8892/POG9048), surgeons adhered to the guidelines (derived from adult epithelial cancer) in only 2% of the patients,[418] but overall EFS and overall survival (OS) rates were nonetheless excellent.[433] Surgical omissions resulting in protocol noncompliance resulted from failure to biopsy bilateral nodes (97%), no omentectomy (36%), no peritoneal cytology (21%), and no contralateral ovary biopsy (59%). Among the patients in whom peritoneal cytology was examined, 25% of patients had malignant tumor found in what would otherwise been declared to be stage I disease. Biopsy of normal-appearing lymph nodes, omentum, and/or contralateral ovary very rarely, if ever, showed occult malignant disease.

Given the excellent overall survival, despite low adherence to the surgical guidelines on the Pediatric Intergroup Trial, the current surgical guidelines for pediatric ovarian GCT have been substantially revised. Given the high rate of positivity in the examination of peritoneal fluid, all patients with ascites present should have the fluid collected for cytology. In the absence of ascites, peritoneal washings should be conducted and sent for pathologic review. Any patient in whom cytology is not available should not be considered to be in stage I. The pelvic viscera should be examined, and pelvic and retroperitoneal lymph nodes should be palpated bilaterally. Only suspicious or enlarged lymph nodes should be biopsied. The omentum and peritoneal surfaces should also be palpated and visualized. If the omentum is adherent or has nodules or implants, partial or complete omentectomy that includes the lesions should be done. If the omentum does not appear grossly involved, an omentectomy does not need to be performed. Any nodules studding the peritoneal surfaces should be biopsied.

If only one ovary is involved, the tumor should be removed by unilateral oophorectomy. Attempts to preserve completely uninvolved fallopian tubes and the uterus should be made in all patients. Lesions adherent to the uterus may be managed by separation of the adherence if feasible or by biopsy only with planned second-look surgery after chemotherapy if necessary. The tumor capsule should not be aspirated. If the capsule is violated, either by the surgeon or because of rupture by the tumor or if there is microscopic capsule penetration seen by the pathologist in an apparently intact tumor, the patient should be upgraded to stage II (this is in contrast to adult staging guidelines in which a patient with capsular involvement is International Federation of Gynecology and Obstetrics [FIGO] stage IC). The ovary must be delivered intact and not removed in fragments. The contralateral ovary should only be biopsied if it appears involved with tumor; biopsy of a normal-appearing contralateral ovary is discouraged because of concern regarding possible adverse impact on future fertility. Bilateral ovarian lesions were present in only 6% of patients (n = 10) on the U.S. Pediatric Intergroup Study. Of these, four were benign teratomas and six were malignancies. If a patient has bilateral disease, preservation of as much normal ovarian parenchyma as possible should be the goal.

Surgical Approach to Mediastinal Germ Cell Tumors

The German MAKEI experience with mediastinal GCTs was analogous to the experience with sacrococcygeal tumors. Delayed resection increased the odds of complete resection of the primary tumor (10 of 11 patients at delayed resection vs. 6 out of 12 patients at primary resection) and complete resection was a strong predictor of more favorable outcome (EFS 0.94 ± 0.06 vs. 0.42 ± 0.33).[417] Therefore the surgeon must decide whether it is more prudent to attempt a primary resection or to obtain a biopsy and plan for delayed resection.

The resection may be through a lateral thoracotomy or median sternotomy, as determined by the site of the lesion. The margin of resection should include adherent nonvital structures such as the thymus and pericardium. Regional lymph nodes should be evaluated and biopsied when possible in all patients.

Surgical Approach to Extragonadal Tumors at Other Sites

YST (also referred to as *endodermal sinus tumor*) of the vagina is a rare tumor occurring exclusively in children younger than 3 years of age. The mass can be confused with sarcoma botryoides. Only small lesions that can be resected with vaginal preservation should be excised at initial presentation. In others, a careful vaginal examination and limited biopsy should be performed. After completion of chemotherapy, repeat evaluation and complete excision of residual disease should be considered, although oftentimes residual tissue is just scar tissue. A biopsy to guide the need for resection is a reasonable approach.

Malignant GCTs found at other locations should be completely excised if possible without sacrifice of adjacent organs. Biopsy only may be appropriate at the initial operation, with planned secondary procedures for delayed excision after chemotherapy. Any enlarged regional lymph nodes in the area should be sampled.

PROGNOSTIC FACTORS AT DIAGNOSIS OF PEDIATRIC GERM CELL TUMORS

Tumor markers have prognostic significance. In pediatric GCT, preoperative tumor markers have been evaluated, whereas in adult testicular cancer tumor markers evaluated at the time of initiation of chemotherapy are used as the benchmark, which is why it is important to obtain preoperative levels. In adult males with testicular cancer, the prognostic significance of tumor markers is well established. IGCCC pooled data on over 5000 men with testicular cancer; multivariate analysis identified prognostic factors that could divide patients into good, intermediate, and poor risk groups. Elevated tumor markers are one of the primary variables that determine risk group assignment in adults. Other adverse prognostic factors include mediastinal primary site and presence of nonpulmonary visceral metastases. LDH has been shown to be prognostic in adult males with testicular cancer but has not been shown to have prognostic significance in pediatric patients, although analyses to date have been underpowered to examine this issue.

Several retrospective studies in adult males with testicular cancer have shown that slower than expected decline in tumor markers after the initiation of treatment predicts both lower EFS and OS.[434-436] In an analysis of adult men with testicular cancer treated between 1986 and 1998 at Memorial Sloan Kettering, those with satisfactory decline in their tumor markers had an excellent 2-year survival rate (EFS 91%; OS 95%) compared with those who had unsatisfactory decline (EFS 69%, OS 72%).[436] A recent randomized trial among patients classified as having “IGCCC intermediate or poor risk” testicular cancer compared standard therapy, four cycles of BEP, to two cycles of BEP followed by 2 cycles of high-dose carboplatin, etoposide, and cyclophosphamide. Although the overall results of the trial did not show a difference in survival between the two arms, in the subgroup of 67 patients with unsatisfactory tumor marker decline, the 1-year durable complete response was 61% for the patients who received high-dose chemotherapy (HDCT) compared with 34% for those who received BEP alone.[437]

Evaluation of the prognostic significance of tumor markers in pediatrics has been limited by relatively small numbers enrolled on clinical trials. Nonetheless in data from the last U.S. pediatric intergroup trial, data from the United Kingdom’s GC2 trial, and from the French TGM85 and TGM90 trials, an AFP of 10,000 IU/L or higher portends a worse prognosis for EFS.[418,438-441] In multivariate analysis of the U.K. data, AFP higher than 10,000 IU/L was a stronger predictor of relapse than site or stage; those with AFP greater than 10,000 IU/L had four times the risk of relapse. In two pediatric studies, AFP was not found to be prognostic, but both analyses were restricted only to patients with extragonadal primaries.[420,442] β-HCG and LDH was evaluated in the U.S. data and not shown to be of prognostic significance when using the cutpoints developed for adult men in the IGCCC data set.[418,438] Extragonadal tumor site was of prognostic significance in the United States, British, and French studies, although it was defined slightly differently in each study. Common to each study was the inclusion of mediastinal site, which is clearly associated with reduced EFS in all studies. Relative impact of other sites of extragonadal disease will require examination in a larger data set. The impact of satisfactory vs. unsatisfactory tumor marker decline has not been evaluated in pediatric patients with GCTs.

TREATMENT

Overview

Survival has improved markedly since the landmark publication by Einhorn in 1979 noting that widely metastatic testicular GCTs were curable with cisplatin-based regimens.[443] In 1981 Einhorn declared that "testicular cancer is the model of a curable neoplasm."[444] As it becomes more and more established, at least from long-term studies of adult men who have been successfully treated for testicular GCTs, that treatment is associated with significant long-term morbidities and even increased chance of mortality, oncologists need to concede that initial cure is not necessarily synonymous with normal life expectancy. Although highly curable, less toxic therapies need to be determined. Many patients require no treatment besides complete surgical resection; chemotherapy can be reserved to salvage only those patients who have recurrence. On the other end of the spectrum it is also apparent that for a subset of approximately 15% to 20% of patients, the standard cisplatin-based regimens are insufficient and more intensive chemotherapeutic strategies must be devised. A key part of future treatment strategies will be the ability to identify those patients at high risk of relapse at the time of their initial treatment and to design chemotherapeutic regimens that increase the odds of long-term survival both by optimal first-line therapies and salvage therapies for those who fail to respond.

Explanation of the Nomenclature

GCTs are generally divided into several categories when treatment is being discussed. The categories include: 1) teratoma, 2) immature teratoma, 3) seminoma/dysgerminoma, and 4) "other malignant" GCTs that include the histologies of YST (or endodermal sinus), embryonal carcinoma, and choriocarcinoma. GCTs can either present as a single histology, such as pure YST, or with a mixture of different histologies including histologies from all four categories (teratoma, immature teratoma, seminoma/dysgerminoma, and "other malignant"). The terminology is somewhat confusing in that a "malignant" GCT is shorthand for a GCT that contains at least one of the other malignant components, which means yolk sac, embryonal carcinoma, or choriocarcinoma. These histologies do have a more aggressive nature; however, both immature teratoma and seminoma/dysgerminoma are also malignant forms of GCTs. The general proviso is that the one must treat the most malignant form of the GCT. However, it is important to keep in mind what other histologies are present. For instance, if there is a significant portion of the original tumor that is mature or immature teratoma at diagnosis, this part of the tumor is not likely to respond to chemotherapy and it will likely be necessary to surgically excise the remaining teratoma at the end of the chemotherapeutic regimen.

Infantile Choriocarcinoma: A Rare but Rapidly Fatal Condition if Not Recognized

Infantile choriocarcinoma is an extremely rare entity that is a medical emergency and requires immediate institution of therapy. The disease is believed to be transplacentally acquired from a focus of choriocarcinoma that has arisen in the placenta as a variant of gestational trophoblastic disease. Choriocarcinoma is composed of cytotrophoblast, syncytiotrophoblast, and extravillous trophoblast, often mixed in random fashion surrounding areas of hemorrhage and necrosis.[69] Vascular invasion is a common feature of choriocarcinomas.

The median age at presentation was 1 month of age (range 0 days to 5 months).[11] Typical symptoms at diagnosis include severe anemia, failure to thrive, hepatomegaly, and seizures. Less commonly, infants can also have with hemoptysis and respiratory distress or signs of precocious puberty.[445,446] Marked elevations of β-HCG are typical (often $>1 \times 10^6$ IU/L).[12]

The disease is rapidly fatal if the syndrome is not recognized. Among 30 cases reviewed by Blohm and Gobel, two cases were diagnosed in stillborn children; in 19 cases, the diagnosis was made after death at postmortem examination.[445] Among those children who succumbed to the disease, the median time from initial symptoms to death was 21 days. Because of the rapid progression of this disease, treatment should not be delayed for histologic confirmation in an infant who shows a markedly elevated β-HCG and a clinical presentation consistent with infantile choriocarcinoma.

Single agent chemotherapy with methotrexate, which is usually sufficient as a single agent to treat gestational trophoblastic disease in the mother has never been curative in an infant with choriocarcinoma; multiagent chemotherapy is required.[447,448] In Blohm's series of 30 children, the five cases successfully treated received multiagent chemotherapy that included a platinum compound, either cisplatin or carboplatin, used in combination with etoposide. However, because of the rapid growth of these tumors, in several cases the platinum-etoposide combination was coupled with methotrexate administered either the week before or after the platinum regimen. Surgical resection of residual masses has been carried out in most patients at the end of the platinum-based therapy. Upfront surgical resection of tumor is definitely not advised in these patients because of the friability of the tumors, the chance of uncontrolled bleeding, and the delay that would be incurred in starting chemotherapy, as well as the usual fragile state of the infant at diagnosis.

If an infantile choriocarcinoma is diagnosed, the mother should also be screened for the disease. In the review by Blohm and Gobel, 60% of the mothers also had metastatic choriocarcinoma (17/30).[445] Since β-HCG is uniformly elevated in this disease, serial screening of the maternal β-HCG should be sufficient, although some physicians have advocated for radiologic examination of likely metastatic sites (lung, liver, brain) as well.

Seminoma and Dysgerminoma

The nomenclature of this subtype of pediatric GCT can be confusing. It is important to recognize that a tumor with the same histologic appearance has a different name depending on the site in which it arose. *Germinoma* typically refers to an intracranial lesion, usually in the pineal gland. *Dysgerminoma* describes a lesion in the ovary. *Seminoma* describes a lesion that arises in the testis.

Seminomas and dysgerminomas are much more common histologies in young and middle-aged adults than in adolescents. Diagnosis of a seminoma/dysgerminoma is exceedingly rare before the onset of puberty. However, in men overall seminomas account for approximately 50% of all testicular cancers, occurring most commonly in the fourth decade (Fig. 63-15).[261]

Because these tumors are exquisitely sensitive to radiotherapy, radiation was an important component of the treatment regimen. In patients with ovarian tumors, radiation resulted in sterilization of the remaining ovary; therefore since the 1980's chemotherapy with cisplatin-based therapy has replaced radiotherapy in the treatment of ovarian GCT. With longer follow-up observation of patients treated with radiotherapy, it became clear that there was reason for serious concerns about induction of secondary malignancies and cardiovascular disease in patients who received radiation therapy. In large prospective study, risk of cardiac events was 2.4 (95% CI, 1.04 to 5.5).[449] Risk of second malignant neoplasm is 2 (95% CI, 1.9 to 2.2).[450] An accepted standard now for stage I disease is surveillance with expected 15% to 20% relapse rate. With seminomas, relapses can occur quite late; 5% occur after 5 years, and there are anecdotal reports of relapses occurring after 10 years. Most pediatric radiotherapists would prefer not to use radiotherapy to treat a seminoma or dysgerminoma because of the risk of late effects; chemotherapy has replaced radiation as first-line therapy.

Treatment of these histologies has never been explicitly studied in pediatric clinical trials given their rarity, and hence treatment recommendations derive directly from the adult experience. The pediatric oncologist who is referred a patient with one of these diagnoses should consult with an adult oncologist and refer to an organization like National Cancer Care Network (NCCN) that maintains updated clinical practice guidelines for these tumors (http://www.nccn.org/).

TREATMENT OF STAGE I MALIGNANT NONSEMINOMATOUS GERM CELL TUMORS

Because much of the understanding about treatment options for pediatric stage I tumors derives from the adult experience, this work is reviewed in the following section.

Active Surveillance of Adult Men with Stage I Malignant Nonseminomatous Germ Cell Tumor Disease

The watch-and-wait strategy of active observation is based on a plethora of data from adult trials of men with stage I malignant GCT. Over 2000 adult patients have been enrolled on clinical trials of surveillance with a median follow-up range of at least 10 years.[451] Relapse rates range from 27% to 35%; 95% of relapses occur in the first 2 years after orchiectomy; almost all patients who relapse have "good risk" disease as defined by the IGCCC criteria; overall survival with chemotherapy is 98% to 99%.

An increasing concern is that patients who undergo surveillance are obligated to serial CT scans at regular intervals, which expose the patients to a dose of radiation that may subsequently be the cause of secondary malignancy. COG recommends scans every 3 months for the first year and every 6 months for the second year after diagnosis. However, a whole-trunk CT scan (chest/abdomen/pelvis) produces a radiation dose of 10 to 30 mSv.[452] It is recommended that exposure be limited to 100 mSv over 5 years.[453] Although it has been suggested that risk related to low doses of radiation may have been overestimated, a recent retrospective cohort study using data from 15 countries estimated that a cumulative exposure of 100 mSV would lead to a 9.7% increase in risk of all mortality from cancer, excluding leukemia, and a 19% increase in mortality because of leukemia.[454] Rustin et al. postulated that five total-body CT scans could therefore induce one second cancer in every 200 patients, which is the risk of death after stage I testicular cancer.[455] Therefore Rustin and colleagues designed a trial in adult men with stage I testicular cancer comparing a surveillance policy of two CT scans over the first year (at 3 and 12 months) with the standard surveillance policy of five CT scans over the first 2 years (3, 6, 9, 12, and 24 months).[455] Patients continued to have frequent clinical evaluations that included measurement of tumor markers and chest radiography (CXR; once per month in the first year, every 2 months in the second year, and every 3 months in the third year). There was no difference in overall relapse rate between the two surveillance groups, no increase in more advanced stage at relapse between the two groups, and no difference in overall survival. A major limitation of the study was that only 10% of the patients were at high risk for relapse on the basis of the presence of lymphovascular invasion (LVI), so it is not clear whether this schedule is vigilant enough for this group of patients. Given the increased radiosensitivity of children to the low-dose of ionizing radiation associated with CT scans, the schedule of surveillance in children with stage I GCTs deserves serious scrutiny.

Factors that Predict Relapse in Adult Stage I Nonseminomatous Germ Cell Tumor Patients on Surveillance Studies. Multiple studies have confirmed that the single most important prognostic factor is LVI, bifurcating risk into low risk (15% to 20%) and high risk (40% to 50%) for relapse. Although embryonal carcinoma is a significant prognostic variable in univariate analyses, its importance in multivariate models is subsumed by presence of LVI. No immunohistochemical markers, including MIB-1, p53, bcl-2, cathepsin D, or E-cadherin have added to the prognostic significance of LVI alone.[456-460]

Retroperitoneal Lymph Node Resection in Adult Men with Stage I Nonseminomatous Germ Cell Tumor

There is no doubt that surgical removal of retroperitoneal lymph nodes is known to comprise the "landing zones" for metastatic disease from the testes is the most accurate way to determine the stage of patient's cancer and is potentially therapeutic as well. Relapse in the surgical field is less than 1% after RPLND. The consensus of a

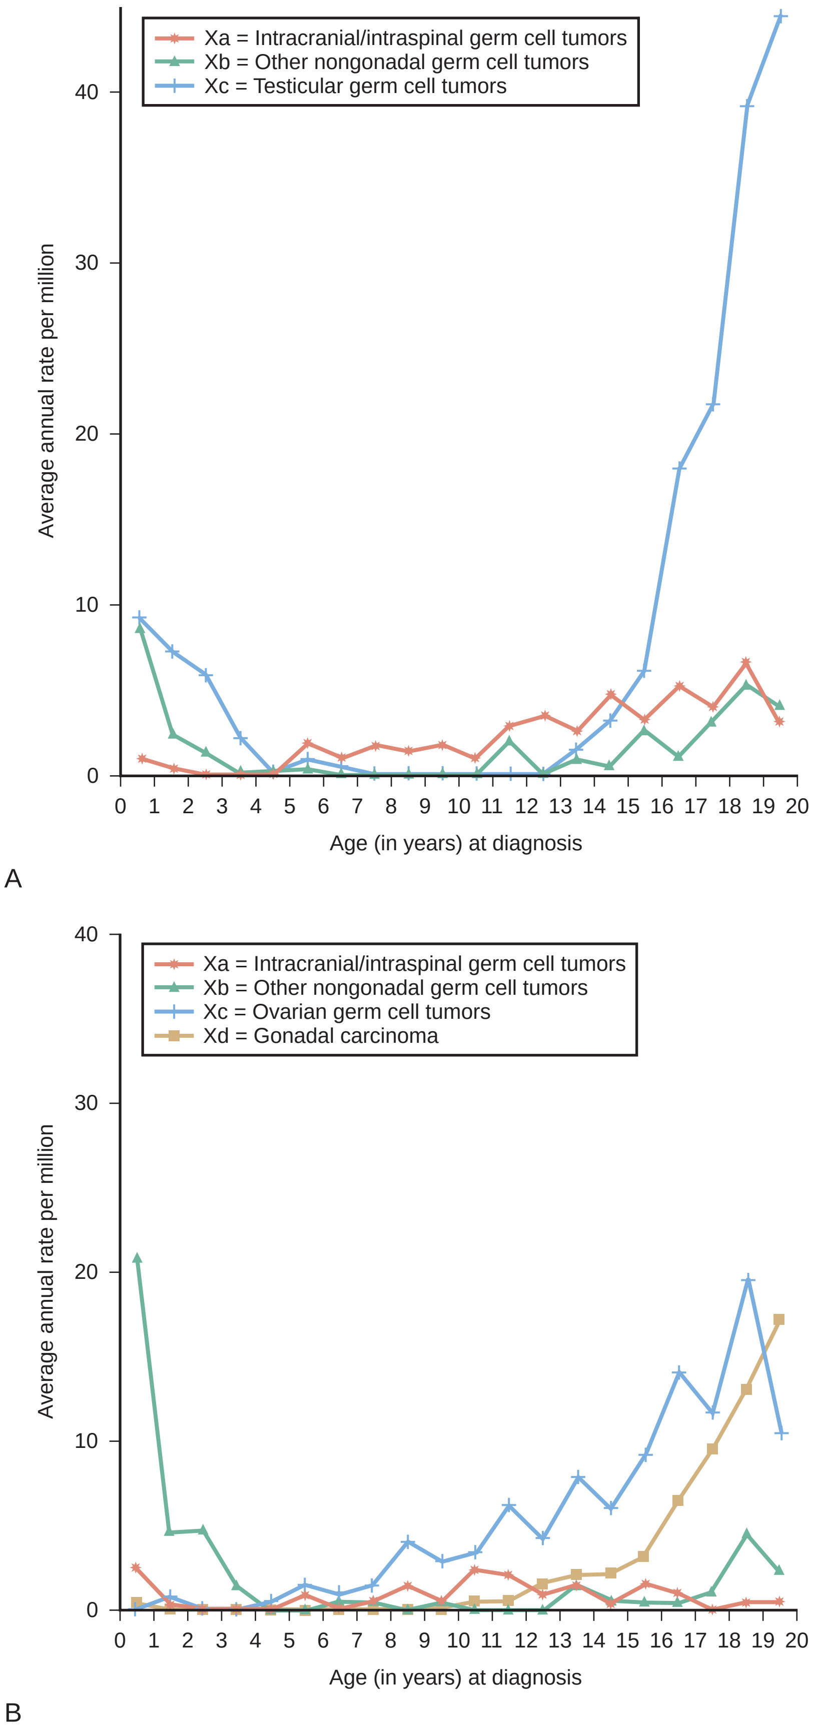

Figure 63-15 Incidence of germ cell tumors in the SEER program from 1973 to 1978 and 1994 to 1998. **A,** Males. **B,** Females. *(From McGlynn KA, Devesa SS, Sigurdson AJ, et al: Trends in the incidence of testicular GCTs in the United States.* Cancer *97:63–70, 2003.)*

series of clinical trials has shown that between 30% and 50% of adult males with testicular stage I nonseminoma have occult metastases at RPLND that were not detected by radiologic scans. Surveillance for patients without an elevation of one of the tumor markers at diagnosis relies heavily on radiologic scans, and some patients prefer the certainty of RPLND in this particular situation.

A serious concern for any patient undergoing RPLND is nerve injury that interferes with the ability to ejaculate, causing retrograde ejaculation, or ejaculatory failure. Because of refinements in surgical technique and the development of so-called "nerve-sparing" approaches, it is estimated that preservation of ejaculatory function is as high as 90% to 95%, especially if the surgery is performed by an urologist who performs a high volume of these procedures per year (i.e., 10 to 20). The surgery can be the cause of uncommon but nonnegligible complications such as bowel complications, lymphocele, and chylous ascites. Referral of the adolescent male who chooses RPLND as primary therapy to a cancer center with a urologist who specializes in RPLND is warranted.

However, RPLND does not mean that chemotherapy will be avoided. Ten percent of patients with pathological stage 1 cancer experience relapse after RPLND (primarily in the lungs) and approximately one third of patients with stage II disease (or 10% to 15% of patients who undergo RPLND) have evidence of sufficiently extensive disease (multiple nodes, any node >2 cm, or any evidence of extranodal spread) that chemotherapy will be initiated immediately after RPLND. Usually at least 2 cycles of BEP is required. One argument in favor of primary (upfront) RPLND is that it may reduce the odds of having to perform RPLND after chemotherapy if there is residual disease. After chemotherapy, the operation is much more technically challenging because of the desmoplastic reaction to chemotherapy. Another advantage of primary RPLND is that it removes any concurrent teratoma, which is a chemoresistant form of GCT. Because a small percentage of teratomas can undergo malignant degeneration to non–germ cell malignancies that are much more difficult to treat, it is beneficial to resect these components of GCT early in course of treatment.

Adjuvant Chemotherapy for Stage I Testicular Nonseminomatous Germ Cell Tumors

Another option employed in men with clinical stage I nonseminomatous germ cell tumors (NSGCT) is adjuvant chemotherapy with one or two cycles of BEP. Although 11 studies have shown that the risk of relapse can be reduced to less than 2%, the concern remains that the majority of patients, conservatively at least 50%, have no further need for chemotherapy after the orchiectomy, and therefore treatment with BEP is overtreatment for a large percentage. Moreover, accumulating evidence of significant long-term side effects associated with three or four cycles of cisplatin-based therapy, including a marked increase in cardiovascular disease and risk of second malignancy (see "Late Effects") should invoke caution about the administration of even two cycles of the same therapy, because the relation between dose and late effect has not been quantified.

Active Observation of Pediatric Germ Cell Tumor Patients with Stage I Disease

On the U.S. Pediatric Intergroup Study (POG09048/CCG8891), boys younger than 11 years of age with stage I testicular malignant GCTs were observed after surgery (watch-and-wait strategy) and only given chemotherapy if tumor markers did not normalize as expected or if imaging revealed recurrent disease. Among the 63 patients enrolled on the protocol, 11 patients had progression of disease and received chemotherapy (four cycles of standard-dose PEB; see the following section on treatment); 80% of the recurrences occurred in the first year after surgery. The 6-year EFS of active observation was 78.5% ± 7%; however, all patients were salvaged with subsequent chemotherapy (6-year OS 100%).[431]

On the subsequent COG GCT study (AGCT0132), an initial strategy of surveillance after surgical resection was extended to girls with pediatric stage I malignant ovarian GCT (MOGCT) to determine whether overall survival could be preserved.[461] Between November 2003 and July 2011, 25 girls, ages 0 to 16 years (median age 12 years old) with stage I MOGCT were enrolled into the trial. Twenty-three patients had elevated AFP at diagnosis. Predominant histology was YST. Twelve patients had evidence of persistent or recurrent disease (EFS 52%; 95% CI, 31% to 69%). Median time to recurrence was 2 months. All patients had elevated AFP at recurrence; six had localized disease, two had metastatic disease, and four had tumor marker elevation only. Eleven of 12 patients with relapse were salvaged with chemotherapy (OS 96%; 95% CI, 74% to 99%) consisting of three cycles of "compressed PEB" (cisplatin 33 mg/m^2 and etoposide 167 mg/m^2 on days 1 through 3, bleomycin 15 U/m^2 on day 1; cycles repeated every 21 days). This trial demonstrated that 50% of stage I pediatric MOGCT can be spared with chemotherapy; a larger study is needed to ascertain whether prognostic factors exist for relapse of ovarian GCT, similar to LVI in adult male testicular cancer, and whether this strategy can be extended to older adolescents and young adults.

In the U.K. Germ Cell Tumor Study II that was conducted between 1989 and 1997, all gonadal (both testicular and ovarian) stage I tumors were observed without chemotherapy. Forty of 51 TGCT patients (78%) and 6 of 9 (66%) patients with ovarian stage I GCT were successfully treated with surgery alone. All patients who experienced recurrence after observation were cured with 4 to 6 cycles carboplatin, etoposide, bleomycin (JEB) chemotherapy. For details of JEB chemotherapy please see the section on treatment.

The Germans have used separate protocols for treating testicular tumors (MAHO protocols) and nontesticular, extracranial pediatric GCTs (MAKEI protocols). In the latest update of the MAHO protocols from 2002, the authors report on results from 1982 to 2001.[423] A watch-and-wait approach was taken for patients with stage I nonseminomatous testicular tumors, but only if the malignant histology was pure yolk sac, pure teratoma, pure immature teratoma, or pure seminoma. Boys with testicular tumors that included a malignant component other than yolk sac were treated with standard chemotherapy that consisted of platinum, vinblastine, and bleomycin (PVB). Of the 140 boys with stage I YST, 16 (13%) progressed and required standard chemotherapy 6 to 60 weeks after orchiectomy.[423] All but one of the 140 patients are alive and well. All boys with either mature teratoma (n = 40), immature teratoma (n = 19), or seminoma (n = 2) were cured with surgery alone.

On the MAKEI96 protocol, the observational strategy was extended to include stage I ovarian and extragonadal GCTs. Excluded from this surgery-only approach were extragonadal tumors that arose in the sacrococcygeal region. Children with primary sacrococcygeal tumors, regardless of stage, were treated with four cycles of cisplatin, etoposide, and ifosfamide (PEI), except for infants younger than 4 months of age, who were treated with four cycles of cisplatin and etoposide (PE; see "Treatment of Pediatric Germ Cell Tumors in Germany"). Results of this approach have not yet been published.

Chemotherapy for Pediatric Germ Cell Tumors (>Stage I)

Prechemotherapy Evaluation

Before initiating chemotherapy, studies should be done to establish a baseline for monitoring toxicity, and procedures should be undertaken to minimize risk of late effects. The postpubertal male patient should be encouraged to use a sperm bank, because a small percentage of male patients will be infertile after chemotherapy. Oocyte cryopreservation (egg freezing) should be considered in postpubertal females because of an ill-defined but apparently increased risk of infertility. In addition, patients who are to receive standard chemotherapy with PEB should have baseline measurements of their renal function by measuring the glomerular filtration rate (GFR), preferably with a chromium ethylenediaminetetraacetic acid (EDTA) clearance, pulmonary function tests (PFTs), including diffusing capacity of the lung for carbon monoxide (DLCO), and baseline audiometry that includes accurate measurements of the high-frequency region, because this is the region that is affected first by cisplatin-induced hearing loss.

History of Use of Chemotherapy Among Adult Men with Testicular Cancer

Treatment of pediatric GCTs derives in large part from knowledge gained in the treatment of adult men with testicular cancer. In 1979 Lawrence Einhorn, MD, reported in *Cancer Treatment Reports* that PVB (also referred to as the *Einhorn regimen*) cured a substantial portion of men with widely disseminated testicular cancer. A follow-up study showed that substitution of etoposide for vinblastine (PEB vs. PVB) was shown to be a superior regimen both in terms of increased efficacy in poor-risk patients and reduced neuromuscular toxicity,[462] and PEB became the standard of care. Finally, it was shown that three cycles of PEB was equivalent to four cycles of PEB among patients with good prognoses as defined by the IGCCC.[463] On this backbone of experience in the treatment of adult testicular cancer, the pediatric trials reviewed in the next section were developed.

Treatment of Pediatric Germ Cell Tumors in the United States

Before the use of chemotherapy, the outcome of children with GCTs was dismal; 3-year survival rates did not reach 20%.[212,464] In the mid 1970s, the first reports of effective chemotherapy regimens for pediatric GCTs were published.[465,466] These regimens were based on vincristine, dactinomycin, and cyclophosphamide (VAC) but also included radiation therapy as well. Although the survival for patients of average risk improved to approximately 60%, children with advanced-stage disease continued to have a very poor prognosis. After the Einhorn regimen of PVB was published in the late 1970s, showing that a high rate of cure was possible for men with metastatic testicular cancer,[443] cisplatin-based regimens were quickly adopted in pediatrics with marked improvement in outcome, even for patients with advanced stage disease. Ablin et al. initiated a regimen in the CCG (CCG861) that combined PVB with the drugs that had previously been shown to have activity: cyclophosphamide, actinomycin, and adriamycin.[453] At 18 weeks, patients in partial remission (PR) received radiation therapy and maintenance chemotherapy until 2 years after diagnosis. This protocol enrolled 93 patients with pediatric germ cell tumors, excluding patients with TGCTs and including patients with ovarian (n = 30), sacrococcygeal (n = 37), and mediastinal tumors (n = 17). Ovarian tumors had a 4-year OS rate and EFS rates of 67% and 63%, whereas extragonadal tumors had lower rates of survival (EFS, 48%; OS, 42%). Even though this protocol did include cisplatin, it was given at a low dose (60 mg/m^2) and dose intensity (every 9 weeks) so that its effectiveness was likely compromised.

Subsequently, the CCG and the POG initiated an intergroup study from 1990 to 1995. The intergroup study divided patients into two risk groups: the low-/intermediate-risk group included stage I/II gonadal MGCT patients (treated on POG9048/CCG8891),[467] and the high-risk group included stage III/IV gonadal MGCT and stages I through IV extragonadal MGCT (treated on POG9049/CCG8892).[433]

On the POG9048/CCG8891 protocol for treatment of low-stage gonadal tumors, only boys younger than 11 years of age were enrolled. Older boys were to be treated according to adult standards. Boys with stage I disease were treated with active observation (see "Treatment of Stage I Malignant Nonseminomatous Germ Cell Tumors"); boys with stage II testicular MGCT (including relapses of initially stage I testicular MGCT) and girls with stage I/II ovarian MGCT younger than 21 years of age received four cycles of standard-dose pediatric BEP (bleomycin 15 U/m^2 on day 1, etoposide 100 mg/m^2/day on days 1 through 5, and cisplatin 20 mg/m^2/day on days 1 through 5). On both the low-/intermediate-risk and high-risk arms of the intergroup study, bleomycin was reduced from a weekly dose used on adult protocols to once per cycle, or every 3 weeks, in order to reduce the incidence of pulmonary fibrosis. Of note, both the British and German investigators have similarly reduced the dose of bleomycin without apparent adverse results. It is important to realize, however, that this reduction in dosage has never been studied in a randomized trial that compares weekly dose, as bleomycin is administered in the adult trials, versus the once-every-3-week regimen introduced by pediatric oncologists. Patients were reevaluated with tumor markers and radiologic scans after four cycles. If either imaging or tumor markers suggested residual disease, patients underwent surgical exploration, and if viable tumor was found pathologically and/or if tumor markers did not normalize, the patient was given an additional two cycles of PEB.[467]

Patients with pure dysgerminoma/seminoma were excluded from the U.S. Pediatric Intergroup Trials. The treatment of pure immature teratoma on the U.S. Pediatric Intergroup Trial is discussed in "Mature and Immature Teratoma."

On the low-/intermediate-risk arm of the study, overall 6-year EFS was 94.5%, and 6-year OS was 95.7%.[467] Six-year EFS and OS by primary site were as follows: testicular stage II (100% and 100%), ovarian stage I (95% and 95%), and ovarian stage II (87% and 94%). Two patients underwent second-look surgery; one patient had evidence of residual malignant disease. Although 23% of patients had grade 3 to 4 hematologic toxicity, no delay in therapy was reported. No patient had grade 3 to 4 ototoxicity, renal toxicity or pulmonary toxicity. Two patients with primary ovarian tumors developed acute myelogenous leukemia (AML) at 5 and 32 months from start of therapy, but neither patient had the topoisomerase-induced 11q23 cytogenetic abnormality.[467]

To follow this trial the COG protocol AGCT0132, was opened in 2002 for low-risk (gonadal stage I patients, both ovarian and testicular) and intermediate-risk (stage II through IV gonadal tumors and stage I/II extragonadal tumors) patients. The aims of this trial were to evaluate a watch-and-wait strategy for low-risk patients, reserving chemotherapy for those who fail observation after surgery (see prior summary of results of the low risk trial). For patients who were judged to be of intermediate risk, the protocol evaluated the efficacy of three courses of PEB (rather than four courses, which had been used on the previous protocol) and whether the drugs can be given in a compressed manner over 3 days rather than over 5 days. Enrollment was completed in June 2012; analyses are ongoing.

The high-risk protocol of the previous Pediatric Intergroup Trial (POG9049/CCG8892) was a randomized clinical trial comparing standard-dose PEB (total cisplatin dose 100 mg/m^2) with high-dose PEB (HDPEB; total cisplatin dose 200 mg/m^2).[433] The results of the prior intergroup high-risk clinical trial for stage III/IV gonadal tumors and stage I to IV extragonadal MGCT did not show a significant difference in 6-year OS between HDPEB and PEB (92% vs. 86%); however, there was evidence of an increase in 6-year EFS among patients receiving HDPEB (89.6% ± 3.6% vs. 80.5 ± 4.8%; %, $P = 0.03$).[433] Overall 6-year EFS and OS by site and stage are as follows: testicular stage III (94% and 100%), testicular stage IV (88% and 91%), ovarian stage III (97% and 98%), ovarian stage IV (87% and 93%), extragonadal stage I and II (89% and 93%), extragonadal stage III (75% and 80%), and extragonadal stage IV (78% and 81%). The study was not powered to be able to examine response by site and stage, but in each subgroup there was a trend towards higher EFS and OS for patients treated with HDPEB. This difference was most pronounced in patients with extragonadal MGCT, in which it achieved borderline statistical significance. Patients with stage III/IV extragonadal tumors treated with HDPEB had a 2-year EFS of 84% compared with 74% for patients treated with standard-dose PEB ($P = 0.09$).

Toxicity was much greater on the HDPEB arm of the study. Fatal infections accounted for 7 deaths on the study, and 6 deaths occurred on the HDPEB arm. Hearing aids were needed in 67% of the patients treated with HDPEB. Three patients who initially had been diagnosed with a mediastinal MGCT developed hematologic malignancies posttreatment. Two patients developed AML; neither had the characteristic 11q23 abnormality usually associated with etoposide-induced leukemias. One patient developed erythrophagocytic syndrome.

Given the trend observed for better survival among patients with high-stage extragonadal GCTs on the HDPEB arm, a follow-up pilot study was designed incorporating amifostine (825mg/m^2/day) with the goal of reducing the observed toxicities of the higher dose of cisplatin, particularly the ototoxicity.[468] Among the 20 patients enrolled, 17 were females, median age was 1.6 years, and the primary site was sacrococcygeal in 15 patients. Although the EFS and OS were acceptable (83% and 85%), amifostine at this dose and schedule did not protect against ototoxicity; 75% of patients had significant hearing loss.

A second pilot study for patients with high-risk advanced stage extragonadal tumors has been completed by COG. In this trial, standard-dose PEB was combined with escalating doses of cyclophosphamide.[469] The three dose levels of cyclophosphamide were 1.2 gm/m^2, 1.8 g/m^2, and 2.4 gm/m^2. Nineteen patients were enrolled; 3 patients were nonevaluable for the assessment of dose limiting toxicity (DLT). Sixteen patients completed four cycles of induction, 11 had complete response, one had progressive disease, and four had a partial response. All four with partial response had a residual mass and underwent second look surgery and then completed two additional cycles of their assigned regimen. Only one patient, enrolled on the dosage of 1.8 g/m^2, experienced DLT during the first cycle of therapy manifested as grade 3 hyperglycemia. No other patient experienced DLT. The 4-year EFS and OS (± standard deviation) were 74% ± 7% and 89% ± 10%, respectively.[469] This observed EFS is not apparently different than what was observed with standard dose PEB in the prior intergroup study.

Treatment of Pediatric Germ Cell Tumors in the United Kingdom

From 1977 through 1988, patients in the United Kingdom were treated on United Kingdom Children's Cancer Study Group (UKCCG) Germ Cell Tumor Studies 1 (GC1).[470] This protocol compared five regimens that were used sequentially over the time interval: low-dose VAC, high-dose VAC, high-dose doxorubicin plus VAC (Adria-VAC), PVB, and PEB. GC1 enrolled 52 patients who received chemotherapy until complete response was documented and then two more cycles after achieving complete remission (CR; CR +2). Outcome varied significantly by regimen; PEB was clearly the most effective.

In 1989 based on preliminary data showing efficacy of carboplatin in pediatric MGCT, the UKCCG initiated their second GCT study (GC2) in which cisplatin was replaced by carboplatin.[471] JEB consists of etoposide 120 mg/m^2/day for days 1 through 3 (total dose 360 mg/m^2); carboplatin on day 2 in at an area under the curve (AUC) of 7.9 (AUC formula: [6 × *uncorrected GFR*] + [15 × *surface area*]), equivalent to approximately 600 mg/m^2; and bleomycin 15 mg/ m^2 on day 3. Clinicians were urged to use the AUC formula to calculate the carboplatin dose rather than use a dose based on surface area, but 75% of the patients enrolled on the study were dosed according to the square-meter dose. It is important to note that this is a higher dose and dose-intensity of carboplatin than used in the French study of carboplatin in pediatric GCTs (TGM90), in which the results with carboplatin were inferior to those in a previous trial that had utilized cisplatin (TGM8589).[472,473] As was the practice with GC1, patients in GC2 received chemotherapy until a complete response was documented and then two further cycles.

The U.K. investigators have published an interim analysis of the patients treated between 1989 and 1997.[471] During this time, 184 patients younger than 16 years of age with either localized or metastatic extracranial GCTs were enrolled in GC2 and eligible for analysis. In total, JEB chemotherapy was administered to 137 patients. GC2 remained open to recruitment after analysis in 1997, and an additional 84 patients received JEB in this period, resulting in a total of 221 patients who eventually received chemotherapy. Patients with gonadal stage I tumors were observed without chemotherapy (watch-and-wait strategy). Forty of 51 patients with TGCTs (78%) and six of nine (66%) patients with ovarian stage I GCTs were successfully treated with surgery alone. All patients who experienced recurrence after observation were cured with JEB chemotherapy. The overall survival for all 137 JEB-treated patients at 5 years was 90.9% (95% CI, 83.8% to 95%) and EFS at 5 years was 87.8% (95% CI, 81.1% to 92.4%). Outcome by site, stage, histologic classification, and initial presurgical AFP level are summarized in Figure 63-6.[75] EFS according to site was 100% for testis, 90.7% for ovary, 86.5% for sacrococcygeal, and 75% for mediastinal. EFS according to stage was 100% for stage I, 93.8% for stage II, 84.8% for stage III, and 78% for stage IV. Toxicity was minimal with JEB. In the GC2 study, only one child had severe deafness (likely attributable to a middle-ear hemorrhage when the child had thrombocytopenia), and none had severe renal toxicity. However, carboplatin is more myelotoxic than cisplatin; 36% of the total number of courses were delayed more than 28 days. Second-look surgery was undertaken in 45 patients (33%) in GC2. Necrotic or fibrotic tissue was found in 24 patients (53%), mature or immature teratoma was found in 19 patients (42%), and only 2 patients were found to have viable tumor.

The United Kingdom Children's Cancer and Leukemia Group (UKCCLG) protocol (GC3) opened in May 2005. This protocol continues to use JEB chemotherapy as first line treatment. Patients with low-risk disease (stage 1 gonadal tumors) are treated surgically with close surveillance. Other patients receive four or six courses of JEB according to risk group stratification determined by site, stage, age, and AFP level. The study has closed; analyses are ongoing but not yet reported.

The results are similar to those reported by the U.S. POG/CCG Intergroup Study[433] and raise the question of whether it is necessary to continue treatment with cisplatin in pediatric patients, given the higher toxicity profile of cisplatin. The concern is that carboplatin has been shown to be inferior to cisplatin in five randomized clinical trials in adults with metastatic "good risk" testicular cancer.[474,475] However, the maximum dose used in the adult trials was 500 mg/m^2, and in two of the trials, the carboplatin was given every 28 days in a less dose-intense fashion.[476] Likewise in pediatric GCTs, the French showed that carboplatin was inferior to previous results of treating with cisplatin (TGM90 vs. TGM85); however both the dose (400 mg/m^2) and dose-intensity (once every 6 weeks) were low on the French trial.[472,473] Consideration of carboplatin as first-line therapy for low and intermediate risk pediatric germ cell patients is warranted.

Treatment of Pediatric Germ Cell Tumors in Germany

The German Society of Pediatric Oncology has used separate protocols for treating testicular tumors (MAHO protocols) and nontesticular, extracranial pediatric GCTs (MAKEI protocols). In the latest update of the MAHO protocols published in 2002, the authors report on results from 1982 through 2001.[477] A watch-and-wait approach was taken for patients with stage I testicular YSTs. All patients with stage I tumors who had a malignant component other than yolk sac, as well as patients with higher than stage I testicular tumors, were treated with "standard chemotherapy" that consisted of PVB (vinblastine 3.0 gm/m^2 on days 1 and 2, bleomycin 15 U/m^2 on days 1 through 3 as continuous infusion, and cisplatin 20 mg/m^2/day on days 4 through 8). Four cycles were given every 28 days. If there was not a complete response after 2 cycles, however, patients underwent exploratory laparotomy, and if viable disease was discovered, patients received four cycles of salvage therapy that consisted of PEI (etoposide 80mg/m^2/day on days 1 through 3, ifosfamide 1500 mg/m^2/day on days 1 through 4, and cisplatin 20 mg/m^2/day on days 2 through 5). If there was no evidence of disease at laparotomy, the patient received two more cycles of the standard PVB for a total of four courses. In toto, 59 patients received chemotherapy with an overall survival rate of 95%. Survival among patients with stage I and II disease was excellent; 41 of 42 patients survived. Among patients with stage III testicular cancer, 5 of 17 patients died despite the use of salvage chemotherapy.

The German MAKEI protocols (MAKEI83/86, MAKEI89, MAKEI96) specifically include only patients with either an ovarian or extragonadal primary tumor and exclude patients with a testicular primary tumor (treated on MAHO). In MAKEI83/86, patients were stratified into either low risk or high risk categories. The low-risk classification included only stage I ovarian tumors; these patients received four cycles of PVB. Patients in the high-risk group had stage II through IV ovarian and stage I through IIb extragonadal primary tumors. These patients received four cycles of PVB followed by four cycles of PEI. Because of concerns about the pulmonary toxicity associated with bleomycin and the neurotoxicity associated with vinblastine in the original Einhorn regimen, a modified Einhorn regimen was developed. Bleomycin was given before cisplatin, because cisplatin had been shown to reduce the clearance of bleomycin, as a continuous infusion over 3 days at 15 mg/m^2/day or 45 mg/m^2 per cycle. Cumulative dose of bleomycin was limited to 180 mg/m^2. This is substantially higher than the total dose of bleomycin patients receive on either U.S. or U.K. protocol, in which the per-cycle dose of bleomycin is only 15 units/m^2, and most patients receive between three and six cycles (or total cumulative dose of 45 to 90 U/m^2. The German dose of bleomycin is more analogous to the cumulative doses of bleomycin one would find on an adult protocol for treating GCTs, in which 30 units of bleomycin is administered weekly for 9 weeks for total cumulative dose on average of 270 units or 135 U/m^2 in a average adult with a body surface area (BSA) of 2 m^2. Vinblastine was administered at 50% the dose of the original Einhorn regimen to reduce the associated neurotoxicity.

In MAKEI89, changes were made to risk stratification, and the overall amount of chemotherapy administered was reduced. Risk level was stratified into three groups. The low-risk category remained stage I ovarian tumor; medium risk included ovarian stages II and III and extragonadal stage I and IIa tumors, and the high-risk group was comprised of extragonadal stage IIb, coccygeal stage I and IIb, and ovarian stage IV tumors. Therapy was reduced for these low- and intermediate-risk groups by 25% compared to MAKEI83/86. Patients in the low-risk group received three cycles of PEB, and patients at medium risk received three cycles of PEB followed by 3 cycles of PIV.

Outcome of the earlier MAKEI trials are as follows: on MAKEI83/86, the low-risk group achieved 94% EFS, whereas the high-risk group achieved 76% EFS. In MAKEI89, EFS on the low-risk arm was 91%, medium risk was 86%, and high risk was 83%. In terms of site, sacrococcygeal tumors had the lowest EFS without much significant change over time (74%, 80%, and 77% in MAKEI83, 86, and 89, respectively), whereas ovarian tumors had the best outcome with significant improvement over time (EFS 77%, 92%, and 90% on MAKEI83, 86, and 89, respectively).

In MAKEI96, several changes have been made to the risk stratification and recommended therapies. Chemotherapy is determined by site, stage, and degree of resection. Bleomycin was removed from all chemotherapy protocols. All patients with ovarian and extragonadal stage I tumors (except patients with stage I sacrococcygeal tumors) are initially treated with a watch-and-wait strategy. Children with sacrococcygeal primary tumors, regardless of stage, are treated with four cycles of PEI (cisplatin 20 mg/m^2/day on days 1 though 5, etoposide 100 mg/m^2/day on days 1 through 3), and ifosfamide 1500 mg/m^2/day on days 1 through 5 as a continuous infusion). Infants younger than 4 months of age with sacrococcygeal primary tumors are treated with four cycles of PE, omitting the ifosfamide. Patients with primary ovarian tumors receive two cycles of either PE (completely resected) or PEI (incompletely resected), and patients with extragonadal primaries receive three cycles of either PE (completely resected) or PEI (incompletely resected). Patients with advanced stage ovarian and extragonadal primary tumors with poor prognosis are treated with four cycles of PEI. If the tumor was not completely excised at the onset of therapy, three cycles of PEI are given and then the patient undergoes resection. Postoperatively, an additional one to four cycles of PEI are administered depending on whether the tumor was completely or incompletely resected. In all MAKEI protocols diagnosis is based on imaging, tumor markers, and histology. In advanced/bulky disease, diagnosis could be based on markers and imaging, and a preoperative chemotherapy could be applied for downstaging.

The Dose of Bleomycin in Treatment of Pediatric Germ Cell Tumors

In adults, investigators have shown that bleomycin can be safely omitted in patients at "good risk" if the patient receives an additional (fourth) cycle of etoposide and cisplatin.[478] Concern about the possibility of bleomycin-induced pulmonary fibrosis has caused pediatric oncologists to evaluate the same issue. The British and American collaborative groups have reduced the dose of bleomycin from once a week to once per cycle (or once every 3 weeks).[433,471] This dose of bleomycin represents a 67% reduction in the total dose of bleomycin when compared to adult regimens. Since the institution of these changes (1989 in Britain and 1990 in the United States), there have been no reported cases of fatal pulmonary fibrosis in over 137 British cases of patients treated with JEB and 373 cases in the United States of patients treated with PEB. On MAKEI89, after two deaths occurred in children younger than age 2 years from pulmonary fibrosis, German investigators no longer treated children under 1 year of age with bleomycin (using instead etoposide and cisplatin [EP]), and children ages 1 to 2 years received half of the standard dose of bleomycin. However, the dose of bleomycin for older children on MAKEI83/86 and 89 was quite significant: 15 mg/m^2/day for 3 days with each cycle (total 45 mg/m^2/cycle). In MAKEI96, bleomycin was omitted entirely from the chemotherapeutic regimens for all patients. No decrement in survival has been observed since its deletion.

Other countries besides Germany have decided to delete bleomycin from use in pediatric patients. A Brazilian study has reported preliminary results using four cycles of EP with 5-year survival rates of 83% in patients at high risk.[479] The Italians also did not use bleomycin in the Italian cooperative study (TCG91), but their regimen, which alternated carboplatin and etoposide with vincristine, dactinomycin, and ifosfamide, produced suboptimal results, particularly in patients with higher stages of disease, compared with other pediatric germ cell trials.[480]

Mature and Immature Teratomas

Complete surgical excision is adequate therapy for pure mature teratomas. Mature teratomas are much more common than immature teratomas. It is estimated that mature teratomas of the ovary, also called *cystic teratoma* or *dermoid cyst,* account for 95% to 99% of all ovarian teratomas. Mature teratomas that contain an element of a malignant GCT (yolk sac, endodermal-sinus, choriocarcinoma, embryonal carcinoma) should be treated according to the guidelines for the treatment of malignant nonseminomatous GCTs discussed previously.

Immature teratomas are made up elements from the three germ layers and graded from 0 to 3 depending on the amount of immature neuroepithelium present in the tumor.[119] Grade has been shown to correlate with both stage and prognosis. Treatment for immature teratoma is more controversial and evolving.

A classic study by Norris et al reviewed 58 adult women with ovarian immature teratomas who had been treated with surgical resection alone and reported that 70% of women who had grade 3 tumors at diagnosis subsequently relapsed.[119] The recommendation was thus made that stage I grade 3 ovarian immature teratomas ought to be treated with chemotherapy.

Concern that the biology and behavior of immature teratoma might be different in childhood than adulthood led the U.S. pediatric oncology groups to investigate whether surgical resection was sufficient for immature teratoma, even among patients who had grade 3 tumors. Between 1990 and 1995, as part of the U.S. Intergroup Pediatric Study (POG9048/CCG8891), 73 patients with immature teratoma who had undergone a gross total resection were enrolled in the study.[168] Central review of grade showed 31.5% were grade 1; 38.4% were grade 2, and 30.1% were grade 3. Primary site of disease included ovarian (n = 44), testicular (n = 7), sacrococcygeal (n = 5), retroperitoneal (n = 7), and head/neck (n = 7). All pathology was centrally reviewed; 50 patients were confirmed to have pure immature teratoma, whereas 21 had microscopic foci of YST and two had microscopic foci of PNET. Because significant time had elapsed between the initial surgery and the central review of the pathology (typically at least 6 months), it was decided to continue to observe patients discovered to have a malignant focus at central pathology review. Tumor markers were elevated in 25 patients at diagnosis (AFP alone, 18; β-HCG alone, 5; both, 2). Overall, only one half of the patients with microscopic foci of YST had an elevated AFP at diagnosis (9 out of 20 patients). However, in ovarian tumors there is a tight correlation between an elevated AFP and presence of YST; 70% of patients shown to have microscopic foci of YST had an elevated AFP at diagnosis, whereas only 25% of patients with pure immature teratoma had an elevated AFP at diagnosis.[130] Elevation of AFP at diagnosis was also strongly correlated with stage and grade of the immature teratoma.[130]

With a median follow-up of 35 months, the overall 3-year EFS was 93%, with 3-year EFS of 97.8%, 100%, and 80% for ovarian, testicular, and extragonadal tumors respectively.[168] Five patients relapsed, all within 7 months of the original diagnosis; one had an ovarian primary tumor and 4 had extragonadal primary tumors. In retrospect at central pathology review, three of the five patients had YST present at diagnosis; one patient had PNET. The patient with PNET who had recurrence was resistant to platinum-based therapy. All of the other patients were successfully treated with PEB.

How to treat pure immature teratoma higher than stage I lacks clinical consensus and published data. There is generally a belief in the pediatric oncology community that the diagnosis of immature teratoma has different meaning and clinical significance in the newborn vs. the peripubertal period. In the newborn period, patients with incompletely resected immature teratomas are usually closely observed, reserving treatment (usually reoperation) for those who have recurrence. Immature teratoma in the peripubertal stage (older child and adult) is generally considered to be a malignant disease that warrants treatment with chemotherapy. Treatment with 3 to 4 cycles of standard-dose PEB is generally recommended for patients with higher than stage I pure immature teratoma in the United States, whereas in the United Kingdom all patients with immature teratoma, regardless of stage, site, and age are observed after surgical resection, even in the face of residual disease.[481]

In Germany, the German Society for Pediatric Oncology and Hematology (GPOH) has prospectively studied all extracranial testicular and nontesticular mature and immature teratomas since 1982 on successive MAHO and MAKEI protocols.[482] All pathology is centrally reviewed at a single institution, and grade of immaturity is classified according to Gonzalez-Crussi.[165] AFP and β-HCG are measured on all patients and by definition have to be within normal limits for age in order to establish the diagnosis of teratoma. Treatment of immature teratoma has varied over time. On MAKEI83/86, patients with incompletely resected immature teratoma grade 2 or 3 were treated with three cycles of VAC chemotherapy. On MAKEI89, chemotherapy (three cycles of PEB) was given to patients with incompletely resected immature teratomas of grade 3.

Overall, the completeness of the original tumor resection was the chief predictor of relapse. EFS after complete resection was 96%, whereas EFS was only 55% among those with incomplete resection at diagnosis. The Germans use a very strict definition of a complete resection. Complete resection of a coccygeal tumor was defined as resection of the tumor with its pseudocapsule and the coccygeal bone in one piece. Relapses occurred in 20% of patients with sacrococcygeal tumors, compared with 7% among patients with tumors at other extragonadal sites and only 2% of patients with ovarian primaries. Relapse rate was similar among patients treated with surgery alone vs. patients treated with chemotherapy on the basis of higher grade of immaturity. However, no malignant components were found at the time of relapse among the seven patients who relapsed after initial chemotherapy, whereas 15 of 29 patients who relapsed after surgery only as first treatment had a malignant component detectable in their recurrence.

Immature teratomas were more likely to relapse than mature teratomas; higher grade of immature teratoma was more likely to relapse than lower grade (grade 0 [mature], 10%; grade 1, 14%; grade 2, 21%; grade 3, 31%.).

On MAKEI96, patients with incompletely resected immature teratomas of grade 2 or 3 were stratified to either a watch-and-wait approach or to two courses of adjuvant chemotherapy. The therapy was switched from PEB to PEI, substituting ifosfamide 1500 mg/m^2/day on days 1 through 5 for the bleomycin. However, because of low accrual, the randomization was stopped in the year 2000, and patients have been treated according to physician preference. 261 evaluable patients were enrolled.[482] Because the criteria for complete vs. incomplete resection were more highly scrutinized, the percentage of incompletely resected tumors rose from 10% to 34% on MAKEI96. However, this change was not associated with a reduced relapse rate in the patients whose tumors were completely resected (4.2%). However, the overall relapse rate decreased from 13.3% to 9.5% over that time. The authors are not certain whether this reflects better surgical procedures or a change in the distribution of the primary site of the tumor. The rates are similar to those reported in other studies.[425] It is easier to achieve a complete resection for a gonadal teratoma. Extragonadal teratomas are often adjacent to or infiltrating vital structures such as the sacral plexus in the case of the SCT or large vessels. Probability of relapse on MAKEI96 was not linked to the histologic grade of immaturity, as it had been on MAKEI 83/86/89. One-half of the relapses on MAKEI83/86/89 had a malignant component, whereas two thirds of the relapses on MAKEI96 had a malignant component, illustrating the malignant potential of the teratoma.

Growing Teratoma Syndrome

Growing teratoma syndrome describes the situation in which tumors are noted to enlarge either during chemotherapy or after chemotherapy in a patient with normalized tumor markers. Often mistaken as progression or recurrence, when these tumors are resected and examined pathologically, these tumors are comprised entirely of mature teratoma. The incidence of this phenomenon has been described in approximately 3% of men with testicular cancer[483] and in as high as 12% of women with ovarian GCT, particularly among women originally diagnosed with immature teratoma.[484] The hypothesized etiology is that the chemotherapy might induce differentiation of residual immature teratoma into a mature teratoma. Median interval between chemotherapy and first detection of growing teratoma syndrome was 9 months in a retrospective study of women with ovarian immature teratomas from the Institut Gustave-Roussy; however, the range extended from 1 month after treatment to 12 years after treatment.[484] The disease usually occurs at the site of prior disease; for instance, women known to have peritoneal deposits of tumor at diagnosis were noted to have peritoneal location for the growing teratoma syndrome. In most cases, the recurrence is treated with surgery only. In cases where total resection is not possible, patients require continued surveillance. These patients can become quite ill if the tumor is not amenable to resection and impinges on organ function. A report in the *New England Journal of Medicine* described disease stabilization in three patients with nonresectable tumors who were treated with a CDK4/6 inhibitor; two patients had stable disease for 18 and 24 months at the time of publication.[362]

Extragonadal Tumors

Mediastinal Tumors

The Germans have reported on the outcome of pediatric mediastinal GCT as a separate entity.[417] Included in their report are all patients treated between 1983 and 1999 on German treatment protocols, including MAKEI83/86, 89, and 96. The authors examined the outcome of both mediastinal teratomas (both mature and immature; n = 21) and malignant GCTs of the mediastinum (n = 26). All the mediastinal GCTs diagnosed in the first year of life were teratomas (Fig. 63-16). The incidence of teratoma declined during infancy and adolescence; seminoma was not observed until after age 10.

Teratomas were surgically resected; no adjuvant chemotherapy or radiotherapy was given. Sixteen of the teratomas were mature; five were immature. All patients with teratoma underwent primary resection; surgery was microscopically complete in 17 of 21 patients. All patients with teratomas, regardless of the completeness of the tumor resection, were cured with surgery only.

Twelve of the 26 patients with MGCT had primary resection of the tumor that was complete in six of the 12. Four of the six patients with incomplete resections subsequently underwent second-look surgery, and all achieved a complete resection of the residual tumor. Eleven patients underwent delayed resection of the primary tumor after preoperative chemotherapy, and a complete resection was achieved in 10 of the 11 patients. Three patients did not undergo resection of the tumor;

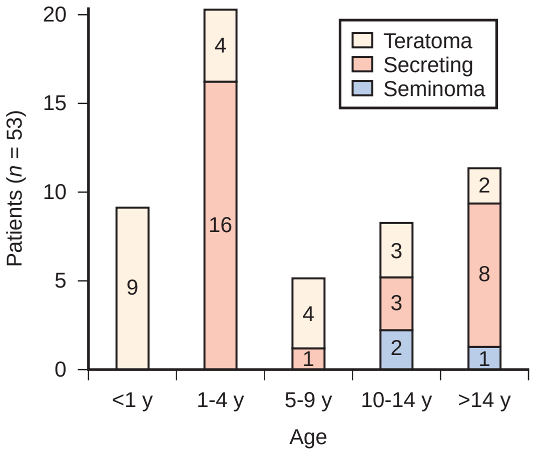

Figure 63-16 Age and histologic differentiation in all registered patients with mediastinal GCTs (n = 53; one patient with insufficient histopathology was excluded). *(From Schneider DT, Calaminus G, Reinhard H, et al: Primary mediastinal germ cell tumors in children and adolescents: results of the German cooperative protocols MAKEI 83/86, 89, and 96.* J Clin Oncol *18:832–839, 2000.)*

TABLE 63-5 Summary of Treatment of Nonseminomatous Malignant Germ Cell Tumors in the United States, Germany, and the United Kingdom

	United States	Germany	United Kingdom
Testicular			
Stage I	W&W[*]	W&W for pure yolk sac Other: 2-3 cycles PVB	W&W
Stage II	3 cycles compressed PEB	2-3 cycles PVB	JEB[†]
Stage III-IV	3 cycles compressed PEB	2 cycles PVB, 4 cycles PEI	JEB
Ovarian			
Stage I ovarian	W&W	W&W	W&W
Stage II	3 cycles compressed PEB	2 cycles PE if completely resected 2 cycles PEI if incompletely resected	JEB
Stage III-IV	3 cycles PEB	4 cycles PEI	JEB
Extragonadal			
Stage I extragonadal	3 cycles compressed PEB	W&W except sacrococcygeal tumors; Stage I SCT: 4 cycles PE, PEI[‡]	W&W
Stage II	3 cycles compressed PEB	3 cycles PE if completely resected. 3 cycles PEI if incompletely resected	JEB
Stage III-IV	High risk protocol	4-5 cycles PEI Poor responder: 1 cycles PEI, 3 cycles HDPEI	JEB
Relapse	TIC +/– stem cell transplant	Local: 4 cycles local deep hyperthermia + PEI Disseminated: 1 cycles PEI, 3 cycles HDPEI	

HDPEI, High-dose cisplatin, etoposide, ifosfamide; *JEB,* carboplatin, etoposide, bleomycin; *PE,* cisplatin, etoposide; *PEB,* bleomycin, etoposide, cisplatin; *PEI,* cisplatin, etoposide, ifosfamide; *TIC,* taxol, ifosfamide, carboplatin; *W&W,* watch-and-wait strategy.

[*] Observation only after surgical excision of Stage I tumor with chemotherapy reserved for those who recur.

[†] 4-6 Cycles; number of cycles determined by risk group stratification.

[‡] Depending on age: <4 months, PE; >4 months, PEI.

two patients had a CR to first-line therapy; and one patient had progressive disease on chemotherapy. Patients were treated with cisplatin-based regimens for a total of three to eight courses (details are shown in Table 63-5).[417] Excellent results on MAKEI83/86 encouraged the German investigators to reduce the maximum number of courses from eight to four or five cycles with no apparent detriment to overall survival. Overall 5-year EFS was 0.83 ± 0.05 at a median follow-up period of 41 months. Complete resection of the tumor either initially, at delayed resection, or at second-look surgery was the strongest predictor of survival. Only one patient of 20 with complete resection relapsed, and that patient was cured with salvage therapy. Analysis of stage of tumor at diagnosis was limited by small sample size, but EFS for patients without distant metastases was 0.93 ± 0.07 vs. 0.65 ± 0.17 for those with distant metastases at diagnosis (P = 0.09). Histology at diagnosis and level of AFP at diagnosis were not prognostic.

Sacrococcygeal Tumors

The Germans have also reported on 71 patients with malignant sacrococcygeal tumors treated in MAKEI83/86 and 89 from 1983 to 1995.[419] Of the 66 evaluable patients, there were 14 boys and 52 girls; median age was 17.4 months. Twelve patients had lymph node metastases, and 30 patients had distant metastases (lungs, 21; liver, 8; bones, 8). On histological examination, 45 patients had pure YST and 21 patients had mixed GCT. Treatment details of MAKEI83/86 and 89 are summarized in Table 63-5. Patients in MAKEI83/86 received a total of eight cycles of cisplatin-based therapy: four cycles of PVB followed by four cycles of PEI. Patients in MAKEI89 received a total of 6 cycles of cisplatin-based therapy: three cycles of PEB followed by three cycles of etoposide, ifosfamide, and cisplatin (VIP). EFS for the entire group was 0.76 ± 0.05, and OS was 0.81 ± 0.05. OS did not differ by protocol (MAKEI83/86 vs. 89) or by stage (T1 vs. T2). The most significant predictor of favorable outcome was the completeness of tumor resection. The completeness of this resection could either be established by tumor resection at initial diagnosis or at delayed resection after chemotherapy is given. Among patients with advanced and metastatic disease (T2b M1), those who had a delayed resection fared better than patients with an initial resection (5-year OS 0.83 ± 0.09 vs. 0.45 ± 0.15; *P* = 0.01). The presence of metastatic disease at diagnosis was only an adverse risk factor among those who had initial resection of their tumor at diagnosis. AFP levels at diagnosis were not prognostic, even when the analysis was restricted to children older than 1 year of age. The authors conclude that the therapeutic strategy of preoperative chemotherapy with delayed resection results in superior outcomes that abrogate prior reports that higher stage and higher pretherapy levels of AFP portend a worse prognosis.

An analysis of the prognostic factors among children with SCT treated on the U.S. intergroup study confirms the conclusions of the German report.[416] Seventy-four children with malignant SCT were randomized to receive either standard-dose PEB or HDPEB. Prognosis was excellent in this subgroup overall (4-year EFS 84% ± 6%; 4-year OS 90% ± 4%). Neither presence of metastatic disease nor delayed resection had an adverse effect on outcome. In this group of patients, AFP greater than 20,000 IU/L was associated with a higher than expected rate of failure.

Postchemotherapy Management

At the end of chemotherapy, full restaging should be undertaken, including radiologic imaging of the primary site and the most likely sites of nodal spread, chest CT, and measurements of tumor markers (AFP and β-HCG). If tumor markers are elevated and chest CT and pelvic/abdominal CT do not reveal the site of metastasis, a bone scan and brain MRI are indicated to look for other possible sites of metastatic disease. In the case in which tumor markers are elevated but no mass is detectable, a PET scan can sometimes be helpful in identifying occult disease. The recommended surveillance postchemotherapy is similar to that recommended for patients with stage I disease (see "Treatment of Stage I Malignant Nonseminomatous Germ Cell Tumors").

Postchemotherapy Retroperitoneal Lymph Node Dissection

If there is either a residual mass detected, surgery is recommended to remove the mass or to explore and biopsy any potentially involved residual lymph nodes. There is limited data on findings from second-look surgeries in children with GCTs. In the United Kingdom after completion of JEB chemotherapy, 45 out of 137 patients required surgery for residual mass seen on radiologic evaluation.[471] Half of the patients (53%) had necrosis or fibrosis; 42% were found to have immature or mature teratoma, and only two patients had viable tumors. The two patients who had viable tumors did not receive any further therapy after complete resection, and both remain in complete remission.

Postchemotherapy Retroperitoneal Lymph Node Dissection in Adult Men with Testicular Cancer

In a retrospective review from Memorial Sloan Kettering, 11% of men who underwent postchemotherapy RPLND had viable residual GCT; 49% had fibrosis, and 40% were found to have teratoma in the postchemotherapy surgical specimen.[437] In the subgroup of patients with teratomas, 85% had pure mature teratomas, 7% had immature teratomas, and 8% had teratomas with malignant transformation (to a non-GCT histology).[437] The median size of the node at postchemotherapy RPLND was 3.0 cm, but 18% of the patients discovered to have teratoma had a node smaller than 2 cm and 11% had a node smaller than 1 cm. The 5- and10-year probabilities of relapse-free survival were 83% and 80%, respectively. There is debate in the adult testicular cancer community as to the optimal surgical approach: a modified RPLND template vs. bilateral infrahilar dissection. The complexity of these issues argue strongly for referral of the adolescent patient to a urologist well-versed in the data.[437,485]

Second-Look Surgery in Ovarian Malignancies

In adult women with epithelial ovarian carcinoma, second-look surgery postchemotherapy is performed on all patients to cytoreduce and has been found to improve prognosis. In adult women with malignant ovarian GCTs, however, it has been shown that the yield of second-look surgery, in the setting of a negative radiologic evaluation and normal tumors markers, has a very low probability of discovering occult residual malignant disease. A report by Gershenson et al. states that only 1 of 53 women with negative scans and tumor markers had viable tumor at second-look surgery.[164]

What should be chemotherapy if tumor is found? Standard of care if viable tumor is found at postchemotherapy lymph node resection has been two more cycles of the original chemotherapy. However, persistence of viable tumor after standard chemotherapy is increasingly viewed as evidence of resistant disease and anecdotally, most adult oncologists are now treating patient with salvage therapy in this setting.

Of note, in adults a higher-than-expected incidence of sarcoidosis has been noted in patients previously treated for GCTs.[434] Sarcoidosis should be considered in the differential diagnosis of any adolescent patient with pulmonary nodules or infiltrates or mediastinal adenopathy in the setting of negative tumor markers.

RELAPSE AND SALVAGE THERAPY

In the German experience, more than 90% of relapses occurred locally.[423] In an analysis of 22 patients with recurrent sacrococcygeal tumors previously treated on the German MAKEI protocols, the majority of patients (17 of 22) presented with local recurrence only. Two patients had only distant metastases, and three patients had combined local and distant recurrences.[346] Most relapses occurred within 6 months of completing primary therapy (median 5.5 months; range 0 to 21 months). Complete surgical resection of the relapse was associated with higher likelihood of continuous CR (5 of 7 patients in first relapse who had a microscopic CR of the relapsed tumor remained in CR). Only 1 of 5 patients who had distant metastases at relapse achieved a second continuous CR. Early vs. late relapse (<1 year vs. >1 year after diagnosis), AFP serum levels at relapse, and tumor size at relapse were not prognostic. These data contrast with those from adult men with TGCT in whom favorable prognostic factors at relapse include IGCCC "good risk" group at first diagnosis, testis as the primary site (vs. retroperitoneal or mediastinal), previous complete response to first line therapy, low tumor markers at relapse, and low-volume disease.

Salvage Therapy

Surgery

Unlike many other forms of cancer, surgical excision can be curative in chemorefractory GCTs in patients who have anatomically confined disease.[486] Most patients also require chemotherapy to achieve a second durable remission.

Chemotherapy

Several different regimens have been used in adult males with relapsed or refractory GCT. Vinblastine, ifosfamide, mesna, and cisplatin (VeIP; vinblastine 0.11mg/kg, cisplatin 25 mg/m^2 × 5, and ifosfamide 1.2 gm/m^2 × 5) results in a complete response in 50% of patients, but responses are durable in only 20% to 30% of cases.[460] More recently, investigators from Memorial Sloan Kettering have reported on a paclitaxel, ifosfamide, and cisplatin (TIP) regimen that substitutes paclitaxel for vinblastine (paclitaxel 250 mg/m^2, ifosfamide 1.2 gm/m^2 × 5, and cisplatin 20 mg/m^2 × 5), in which up to 70% of patients experience CR with durable CR rate of 63%.[487] Oxaliplatin and gemcitabine have both shown activity in phase II trials as single agents in men with relapsed testicular cancer.[488-490] Two recent single-institution reports of treatment of relapsed patients with high-dose chemotherapy (HDCT) have shown encouraging results. Kondagunla et al reported on the treatment of 48 patients with a poor response to standard BEP therapy who were treated with two cycles of paclitaxel and ifosfamide followed by three cycles of carboplatin and etoposide with peripheral blood stem cell (PBSC) support administered at 14-to 21-day intervals.[491] CR was obtained in 55% of patients, and 51% remain in remission at a median follow-up period of 40 months. Einhorn et al reported on the treatment of 184 patients with relapsed testicular cancer who were treated with two cycles of carboplatin and etoposide with PBSC support.[492] CR was obtained in 63% of patients with median follow-up time of 48 months; a high response rate was observed even among the subset of patients who had cisplatin-refractory disease, or had failed prior salvage regimens.

Limited data exist on optimal therapy for pediatric patients whose GCT has relapsed. A trial of paclitaxel, ifosfamide, and carboplatin (TIC; paclitaxel 135 mg/m^2, ifosfamide 1.8 gm/m^2 × 5, carboplatin 560 mg/m^2) is under investigation in the COG. The decision was made to use carboplatin rather than cisplatin for two reasons. First, children are more sensitive to the ototoxicity of cisplatin, and it is likely that many children would have serious hearing impairment if further courses of cisplatin were administered after PEB. Secondly, carboplatin has been shown to be potentially equally as efficacious as cisplatin in children with GCTs in the GC2 study conducted in the United Kingdom.[471] The study is evaluating response to two cycles of TIC. Additional therapy after two cycles of TIC (for instance, either to continue with TIC or to proceed to HDCT with stem cell transplant) is left to the physician's discretion.

Radiotherapy

Radiotherapy is not a standard part of salvage therapy in the United States and certainly not until standard second-line therapy has been attempted. However, in an analysis of outcome of patients with sacrococcygeal GCT tumors treated in Germany, Schneider et al report that 8 out of 22 patients received local irradiation after relapse, most in the situation of an incompletely resected tumor. None of the patients who received less than 45 Gy achieved a stable second CR, whereas 3 of 5 patients who received more than 45 Gy achieved a stable continuous remission.[346]

The Germans have also used regional deep hyperthermia successfully in the control of local recurrence, especially if it is applied early in the course of recurrence.[493] Cisplatin is a thermosensitizer, and thus this approach may be of use in overcoming cisplatin-resistant tumors.

Molecular Basis of Cisplatin Sensitivity and Resistance in Germ Cell Tumors

Compared to most other malignancies, GCTs are unusually responsive to chemotherapy, especially to cisplatin-based regimens (with the exception of teratomas, which are chemoresistant). The reasons for this exquisite sensitivity are not fully known, precluding a complete understanding of the mechanisms of cisplatin resistance, and hampering efforts to overcome chemoresistance in GCTs. Several features of GCTs are thought to contribute to their relative chemosensitivity.[494,495] In particular, GCTs may differ from other malignancies regarding uptake, efflux, and conjugation of cisplatin, as well as the cellular DNA repair and apoptotic response to cisplatin exposure. Uptake of cisplatin into GCTs may occur by passive or facilitated diffusion. Recent work has highlighted the role of copper transporter *CTR1* in cisplatin uptake, and the significance of altered *CTR1* expression in cisplatin-resistant solid tumors.[496-498] However, it is unclear whether *CTR1* significantly affects cisplatin uptake into germ cells. Similarly, overexpression of proteins capable of exporting cisplatin, such as lung resistance protein (LRP) and multidrug resistance-related protein (MRP) 2 is not a consistent feature of cisplatin-resistant GCTs.[494,495,499,500] Conjugation of cisplatin to glutathione can limit its cytotoxicity and facilitate export; in germ cells this conjugation is mediated principally by the isoform of glutathione-*S*-transferase (GST) θ.[501-503] Strohmeyer et al reported an overall low level of GST enzyme activity in GCTs, and Mayer et al found consistent GST-θ expression in only 5 of 36 nonteratoma GCTs.[494,502] Thus low levels of GST activity may contribute to the activity of cisplatin in GCTs. However, in the Mayer et al study the differences between cisplatin-responsive and refractory tumors were not significant.

In the absence of compelling evidence that import or export mechanisms predominantly determine cisplatin's effect on GCTs, attention has focused on the role of DNA damage repair and apoptosis pathways in cisplatin-mediated cytotoxicity. Cisplatin causes bulky DNA adducts, which are removed via nucleotide excision repair (NER).[504] Most GCT cell lines exhibit low NER activity, which may be attributable to low expression levels of the NER proteins XPA, XPF, and ERCC1.[505-507] However, one study found no difference in *XPA* expression between cisplatin-sensitive and resistant tumors,[508] and restoring *XPA* expression to a testicular tumor cell line did not increase cellular resistance to cisplatin,[509] calling into question whether NER is an important factor in GCT response to cisplatin. Another DNA damage-repair pathway, mismatch repair (MMR), has also been investigated in relation to cisplatin treatment of GCTs. A hallmark of defects in the MMR pathway is the presence of microsatellite instability (MSI). Several studies have indicated a low level of MSI in GCTs, implying that the MMR system is generally intact in these tumors.[378,510,511] In the presence of DNA damage, the MMR pathway can trigger p53-dependent apoptosis,[512,513] and this response may explain the sensitivity of most GCTs to cisplatin. On the other hand, loss of MMR may confer chemoresistance. In one series, only 6% of unselected GCTs displayed MSI, whereas 45% of chemoresistant tumors exhibited MSI or low levels of MMR proteins.[378] In another study of GCTs, Velasco and co-workers found that low MMR expression and a high degree of MSI were associated with chemotherapy resistance, shorter time to recurrence, and poor survival.[514] Loss of MMR function is associated with genomic instability and the acquisition of secondary mutations that may enhance tumor survival or aggressiveness.[451,515,516] Thus the MMR system is an important determinant of cisplatin sensitivity in GCTs, and loss of MMR may signal a worse prognosis.

As mentioned, the MMR pathway not only functions to maintain genome integrity but is also one of the factors that triggers apoptosis in response to genotoxic damage such as that caused by cisplatin. Apoptosis, or programmed cell death, is a key determinant of the death or survival of cancer cells and the effectiveness of chemotherapy.[517-522] The tumor-suppressor protein p53 plays a central role in coordinating the apoptotic response to genotoxic damage,[523,524] and attention has focused on the role of the p53 pathway in chemotherapy of GCTs. Mutations in p53, which are commonly found in other tumor types, are rare in GCTs.[494,525] The presence of high levels of wildtype p53 protein in GCTs has been suggested to account for the unusual chemoresponsiveness of these tumors.[526,527] However, p53 deficiency per se does not prevent an apoptotic response to cisplatin in GCT cell lines,[528] and the presence or absence of wildtype p53 correlates poorly with clinical response to chemotherapy.[525] Thus the importance of wildtype p53 expression in determining the cisplatin response of GCTs is not clear. Also unclear is why GCTs treated with cisplatin predominantly exhibit apoptosis rather than undergoing cell-cycle arrest, senescence, or other p53-mediated responses. Despite the absence of p53 mutations, other mechanisms exist in GCTs to interfere with p53 function, including overexpression of the p53 inhibitor MDM2[529,530] and epigenetic silencing of p53 target genes.[531] Particularly interesting in this regard is the recent finding that the miR cluster miR-371-3 acts in GCTs to neutralize the p53 response to oncogenic stress.[295] In summary, there is suggestive evidence that specific features of GCTs, including their retention of a normal DNA damage repair, p53, and apoptosis pathways, may account for the unusual chemosensitivity of these cells. However, a simple loss of these mechanisms does not seem to account for the majority of cases of chemoresistance. Recently, CGH analysis has revealed genomic CNV of specific chromosomal regions associated with acquired cisplatin resistance,[532,533] and further exploration of the genes involved in these regions may shed light on the mechanisms underlying resistance.

Prospects for Targeted Therapy of Germ Cell Tumors

Cisplatin-based chemotherapy of GCTs has been highly effective and will continue to be a mainstay of treatment. However, the toxicity of these regimens, as well as the poor prognosis of cisplatin-resistant disease, points up the need for more specific, effective therapies. Such therapies will depend on advances in research focusing on the molecular mechanisms of germ cell tumorigenesis. To date, these mechanisms are only incompletely understood, but some case reports and small trials have raised intriguing prospects for targeted therapy of GCTs. The receptor tyrosine kinase *c-kit* oncogene is commonly overexpressed in seminomas, and activating mutations in *c-kit* have been described in seminomas,[199,243,372] suggesting that GCTs may be susceptible to treatment with the kinase inhibitor imatinib. Whereas case reports have documented efficacy of imatinib in seminoma[534] the majority of the described *c-kit* mutations in seminomas are insensitive to imatinib,[370] and a phase II trial of imatinib in six patients with *c-kit*–positive metastatic GCT failed to show significant antitumor activity.[490] Although *c-kit* remains a promising target in GCTs and other malignancies, it is clear that not all *c-kit* mutations will be susceptible to imatinib or other tyrosine kinase inhibitors (TKIs) currently in use.[535] Another potential TKI target, the epidermal growth factor receptor (EGFR) has also been investigated in relapsed or refractory GCTs. Several studies reported that EGFR is expressed in nonseminomas,[422,536,537] and a phase II study has been initiated to treat GCTs with erlotinib, a small-molecule EGFR inhibitor. Early reports that GCTs overexpress HER2/Neu and might be susceptible to trastuzumab (a chimeric anti-HER2/Neu antibody)[439] were not borne out by subsequent analyses.[538]

Differentiation therapy is another potential route to targeted therapy of GCTs. Based on the differentiating effect of retinoic acid on GCT cell lines in vitro, 16 patients with chemoresistant GCTs were treated with retinoic acid; no partial or complete responses occurred.[539]

Inhibition of tumor angiogenesis is a promising avenue under intense investigation for many tumor types. In GCTs, increased expression of the proangiogenic vascular endothelial growth factor (VEGF) correlates with tumor metastasis.[540,541] Trials are underway to evaluate the effect of inhibiting VEGF in patients with GCTs by using the small-molecule TKI sunitinib or the combination of oxaliplatin with the anti-VEGF antibody, bevacizumab.

It is important to note that most targeted therapy trials are based on preclinical models of adult GCTs; because the molecular pathogenesis of pediatric tumors likely differs from that of adults, targeted therapy developed for adult GCTs may not translate directly into clinical efficacy in children. More effort is required to define the "targets" for pediatric GCTs and to develop animal models that accurately model the human tumors. In both children and young adults, GCTs appear to arise from defects in early development.[1] Therefore particular attention should be given to examining developmental and stem-cell pathways such as the Wnt/β-catenin, BMP, notch, and hedgehog pathways. Intriguingly, a recent report describes activation of the Wnt/β-catenin pathway in immature teratomas and YSTs but not germinomas, embryonal carcinomas, or choriocarcinomas.[385] The emerging role of miRs in human cancer is another area with potentially great implications for understanding GCT pathogenesis.[390,542,543] Continued progress in molecular cytogenetics and pathway discovery in pediatric GCTs will be critical to the development of improved therapies.

LATE EFFECTS

There is limited data on both the short- and-long term side effects of treatment for GCTs among patients treated as children. GCTs are not included in the Childhood Cancer Survivor Study (CCSS), an invaluable source of information about late effects among children treated for other diagnoses. The only comprehensive survey of late effects of pediatric GCTs is a single-institution study from St. Jude's of 73 patients treated from 1962 through 1988; two thirds of patients had at least one major complication.[544] This study is limited for several reasons; first, the treatment of GCTs has changed radically since 1962 and even since 1988. In the era of the St. Jude study, the majority of patients received radiotherapy as part of their treatment; radiotherapy is seldom used today. The chemotherapy for GCTs during this era included VAC either alone or in combination with a cisplatin-based regimen. The inclusion of an alkylator, cyclophosphamide, in the older regimens radically changes the profile of expected toxicities. Cumulative doses of drugs were also much higher on the older regimens, because "maintenance" therapy often continued for a year, whereas total duration of current regimens is generally only 9 to 12 weeks. For these reasons, the toxicities described in the St. Jude report, such as the high prevalence of delayed pubertal development and ovarian failure, are related to either radiation or treatment with an alkylators, neither part of standard care today.

Other pediatric studies have focused primarily on short-term toxicity either occurring during the clinical trial or within the window of follow-up observation used to establish relapse rate. For instance, among 33 children treated with PEB in the GC1 study in the United Kingdom, 45% developed some degree of renal impairment and 10% developed auditory impairment (grades 1-3). One child developed AML while receiving PEB. There have been no deaths from bleomycin-induced pulmonary fibrosis after the dose of bleomycin was reduced to once per cycle every 3 weeks. There had been four deaths from pulmonary toxicity among children receiving weekly bleomycin. Of the 17 evaluable patients with SCT, four had neuropathic bladder and/or bowel and one child had shortening of one leg.[470,471] Among the 137 patients treated on GC2, which replaced carboplatin for cisplatin, only one patient had significant hearing loss, but this occurred after middle ear hemorrhages, and only patient died of pulmonary failure, and that patient had preexisting bronchopulmonary dysplasia.[470] All other renal and pulmonary toxicity noted on study was reversible. On the U.S. intergroup study, no patient died of pulmonary toxicity.

Late Effects Among Men Treated for Testicular Cancer

Physicians who care for long-term survivors of pediatric GCTs must be aware of and extrapolate from data emerging from follow-up studies of men treated for testicular cancer. Studies of adult men treated for testicular cancer are consistently demonstrating an increased risk of both cardiovascular disease and second malignant neoplasm. However, the limitations of this approach are twofold. One is that age at treatment likely has an important bearing on type and severity of toxicities. For instance, adults are much more likely to develop tinnitus or Reynaud phenomenon after cisplatin than children. Younger age at treatment, however, increases the risk of development of second malignant neoplasm. A concern about extrapolating from the data on men who have been treated with testicular cancer is that one must assume that the experience of men can be applied without revision to the experience of women, an assumption proven to be false in other clinical scenarios.

Cisplatin Levels Are Measurable for Years After Treatment

Cisplatin is a derived from platinum, a heavy metal like iron or lead. Recently it has become apparent that cisplatin is not completely excreted after treatment but is stored and slowly leaches back into the circulation over time. At autopsy, cisplatin can be measured in every tissue of the body,[545] and cisplatin levels are measurable for years after treatment.[546] In 45 patients, platinum plasma concentrations ranged between 1.42 and 2.99×10^{-3}ng/L.[547] Among adult testicular cancer survivors, the circulating level of cisplatin is highly correlated with the amount of persistent neuropathy reported after treatment.[548] The correlation of cisplatin levels with second malignant neoplasm (SMN) and cardiovascular disease has not been reported to date.

Risk of Cardiovascular Disease

In a nationwide cohort in the Netherlands of 2707 5-year survivors of testicular cancer, the standardized incidence ratio of myocardial infarction, angina pectoris, or congestive heart failure was 1.4.[549] In another study of long-term survivors, the relative risk (RR) of cardiovascular disease was estimated to be 2.59 for patients treated with chemotherapy compared with patients under surveillance (with median follow-up period of 10 years).[550] A partial explanation for this excessive morbidity and mortality is the higher prevalence of cardiovascular risk factors among survivors, including a 30% incidence of metabolic syndrome including hypertension, dyslipidemias, obesity, insulin resistance, and gonadal dysfunction[546,551] as compared with either patients treated with surgery and surveillance only or with normal population controls. However, the reason that patients treated with chemotherapy have higher prevalence of cardiovascular risk factors is not well understood. A possible factor contributing to cardiovascular morbidity may be the chemotherapy induces vasospastic disease, as evidenced by the high incidence (up to 50%) of Raynaud phenomenon postchemotherapy in adult survivors of testicular cancer.[552-555] Another explanation for premature onset of cardiovascular events may be direct damage to the endothelial cell. Evidence of endothelial cell damage is the high prevalence (22%) of microalbuminuria observed in long-term survivors.[556] Other authors report an increase in levels of von Willebrand factor in plasma and in the intimamedia thickness of the carotid artery after treatment as further evidence of endothelial cell toxicity.[557]

Risk of Second Malignant Neoplasm

Several studies of the risk of second malignancy among adult men treated for testicular cancer have been conducted.[450,558,559] In the first two studies published (n = 1025 and 1909) an increased risk of secondary malignancy, principally gastrointestinal cancers, was observed, but secondary cancers occurred only in patients who had received radiotherapy.[558,559] A subsequent study that utilized population-based cancer registries identified 40,576 survivors of testicular cancer who had developed a total of 2285 secondary solid cancers.[450,560] In this cohort, patients treated with chemotherapy alone exhibited a 1.8 fold excess risk of developing a second solid cancer, unlike prior studies in which risk appeared to be restricted to those who had been treated with radiotherapy. Treatment with radiotherapy did incur a higher risk (RR 2.0) than that observed with chemotherapy alone, and a synergistic effect between chemotherapy and radiation therapy was also observed (RR 2.9). This study was also the first to report an increased risk of supradiaphragmatic cancers (esophagus, pleura, and lung). Interestingly, cumulative risk at any given age increased with decreasing age at testicular cancer diagnosis. The authors estimated that a patient diagnosed with seminoma at age 20 would have a cumulative risk of solid cancer of 47% by age 75, compared with 36% for patient diagnosed at age 25 and 28% for a patient diagnosed at age 50. There was no plateau in the upward trend for risk throughout the 40 years of follow-up study, with serious implications for those diagnosed and treated at a young age.[450]

Risk of Secondary Leukemia

The development of secondary leukemia or myelodysplastic syndrome after treatment with epipodophyllotoxins is a well-described clinical syndrome usually involving a translocation of the *MLL* gene.[561] The risk of secondary leukemia among adult patients with testicular cancer has been estimated to be 0.6%.[562,563] An analysis of data that included children treated on the last U.S. intergroup national protocol for pediatric GCTs estimated the risk to be virtually identical (0.7%).[561] In a report of the German pediatric experience, 442 patients received chemotherapy, and 174 patients received chemotherapy and radiotherapy.[564] Six patients subsequently developed AML; four of the six had the classic cytogenetic abnormalities associated with topoisomerase II inhibitor-induced leukemias. Cumulative risk at 10 years for AML was 1% for children treated with chemotherapy alone and 4.2% for children treated with both chemotherapy and radiotherapy.

Other Significant Late Effects

Bleomycin and Pulmonary Toxicity

Bleomycin is known to cause fatal pulmonary fibrosis in 1% to 2% of patients, but all patients experience some measurable decrement in pulmonary function while undergoing treatment. However, in adults, almost universally, pulmonary function tests recover to pretreatment values after completion of treatment.[565] Of more concern is the development of rapidly fatal adult respiratory distress syndrome (ARDS) in long-term survivors after general anesthesia. High concentrations of inspired oxygen have been implicated.[566,567] However, in a study reporting on the surgical management of patients that had been treated with bleomycin, the most significant predictor of postoperative oxygen saturation was the amount of blood transfused; intraoperative fractional oxygen was not significant in multivariate analysis.[568] These authors suggest that careful and conservative fluid management is at least as important as restriction of inspired oxygen during surgical procedures.

Most pediatric protocols have either deleted or significantly reduced the amount of bleomycin used so as to completely avoid the complication of fatal pulmonary fibrosis. It is not known how the reduction in dose will affect the development of ARDS during anesthesia post-treatment, and pediatric patients should be made aware of the risk.

Renal Toxicity

The glomerular filtration rate is decreased during treatment in almost all adult male patients, but most studies report restoration of renal function to approximately 85% of pretreatment value by 4 years off therapy.[475,565,569-571] Persistent salt-wasting (Ca, Mg, phosphate) has been reported in 20% of patients.[475,570] Men have also been reported to have elevated renin and aldosterone after therapy.[572]

Gonadal Function

Abnormal sperm counts and motility, and elevated follicle-stimulating hormone (FSH) indicative of impaired spermatogenesis have been documented in two thirds of men after orchiectomy and before any adjuvant treatment.[573,574] One study showed a similar clinical picture even before the initial orchiectomy.[571] Despite these abnormalities in spermatogenesis at diagnosis, a significant proportion of men recover both sperm number and function after treatment.[573,575,576] In one study, 50% of men who were azoospermic at baseline recovered sperm counts to at least 10×10^6 /mL, and 80% of patients who were oligospermic recovered normal sperm counts.[577] Elevated FSH (>2× upper limit of normal) was predictive of abnormal semen analysis both at baseline and also after treatment.[577] Semen recovery usually occurs in the first 2 years after completion of treatment, but improvement has been observed as late as 4 years after treatment.[571] Encouragingly, paternity rates posttreatment are quite high; most men (67% to 76%) who wished to father a child have succeeded.[578]

Persistent endocrine dysfunction has been documented in men after treatment for testicular cancer, particularly in the pituitary-gonadal axis.[553] Several authors note elevations of FSH (up to 75% of men), luteinizing hormone (LH; up to 50% of men).[208,553,569,579] and decreased testosterone (10% to 15%) in long-term survivors of testicular cancer.[553] One author noted that the volume of the remaining testis was reduced in those men who received chemotherapy compared with those who underwent surgery only.[580] Moderate testosterone deficiency, as documented in some long-term survivors, may have a broader systemic impact. For instance testosterone deficiency has been correlated with higher levels of serum cholesterol,[581] and lower testosterone levels are associated with lower levels of bone mineral density.[582] Site apparently was not related to endocrine dysfunction; patients with extragonadal primary tumors had the same profile of endocrine abnormalities.

CONCLUSIONS

Pediatric GCTs are a highly curable form of cancer. Several challenges remain. One objective of current research is to elucidate a better understanding of the underlying biologic etiology of these tumors. Work is also underway to improve upon the current ability to predict who is likely to fail first-line therapy. Better prognostication will allow a more refined approach to therapy, reducing the amount of therapy needed for those likely to be cured. Given the seriousness of the emerging late effects of therapy on rates of cardiovascular disease and SMN in men treated for testicular cancer, physicians must reweigh the risks of adjuvant chemotherapy versus either observation or primary RPLND. Conversely, the field is also challenged to find ways to intensify therapy for those for whom standard therapy is not sufficient. Finally, it is imperative that researchers and practitioners catalogue the late effects of treatment for children with GCTs so that they can adequately care for the majority of pediatric patients who will be cured.

CHAPTER OUTLINE

TYPES OF DENDRITIC CELLS
ORIGINS OF DENDRITIC CELLS
LANGERHANS CELL HISTIOCYTOSIS
Incidence
Clinical Features
Management
Refractory Langerhans Cell Histiocytosis
Reactivation
Long-Term Consequences
Overview of Therapeutic Options
NON–LANGERHANS CELL HISTIOCYTOSES
Juvenile Xanthogranuloma
Sinus Histiocytosis with Massive Lymphadenopathy
MONOCYTES AND MACROPHAGES
Origins of Macrophages
HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS
Incidence
Clinical Features
Familial Hemophagocytic Lymphohistiocytosis
Secondary Hemophagocytic Lymphohistiocytosis
Management
CONCLUSIONS

The histiocytoses constitute a collection of rare hematologic diseases that resist easy classification, at least in part because of the imprecise definition of "histiocyte." "Histiocyte" broadly refers both to cells of the macrophage lineage and to dendritic cells (DCs), only some types of which are derived from macrophages. The numerous descriptive and functional subsets of macrophages and DCs only add to the confusion. Nonetheless, their collective consideration is justified by a degree of uniformity in these childhood diseases that present with infiltration of bone, secondary lymphoid organs, or the liver, with or without concomitant involvement of other visceral organs. However, prognosis and treatment options are specific to the subtype, and thus an appreciation of the individual varieties of histiocytoses is mandatory.

This chapter is divided into two main sections that correspond to the two most common clinical histiocytic disorders, Langerhans cell histiocytosis (LCH) and hemophagocytic lymphohistiocytosis (HLH). Also included is a relatively brief discussion of non–Langerhans cell histiocytoses and Rosai-Dorfman disease. Each section will begin with a description of the normal counterpart(s) of the relevant histiocytes and their ontogeny to provide a context for describing how these cells are pathologically involved in the histiocytic disorders. Each section will also include a description of their clinical manifestations and current approaches to treatment.

TYPES OF DENDRITIC CELLS

The pathologic cells of LCH share some features with normal epidermal Langerhans cells (LCs), which are the primary antigen-presenting cells (APCs) of skin.[1] LCs are one type of the general class of APCs known as DCs because of the characteristic dendritelike structure they assume when activated. DCs are, in turn, just one of several types of APCs that are called "professional" because they can, by themselves, fully activate naive T lymphocytes by providing both the antigen/major histocompatibility complex ligand for T-cell receptor binding and the accessory signals required for full activation.[2,3]

Because DCs can also render T cells tolerant to specific antigens,[4] they have become a major focus of basic immunologic research. This research has revealed a surprising level of functional and phenotypic diversity among DCs, which will undoubtedly be relevant to the proliferative disorders affecting these cells. Several authors have provided helpful guides to thinking about and classifying DCs.[2,3,5,6] Overall, DCs can be divided into conventional and inflammatory types (Box 64-1). Conventional DCs are present in lymphoid and nonlymphoid organs in their basal state, and their primary function is to collect antigens for presentation to T cells in order to activate or tolerize them, depending on the antigen's source (i.e., nonself vs. self). Inflammatory DCs arise in response to

Box 64-1 **Dendritic Cells**

CONVENTIONAL DENDRITIC CELLS

MIGRATORY DENDRITIC CELLS

Migratory dendritic cells (DCs) gather antigen in peripheral tissues, then migrate to regional lymph nodes to present antigen to T lymphocytes

Examples: Langerhans cells, dermal DCs, interstitial DCs

LYMPHOID TISSUE DENDRITIC CELLS

Lymphoid tissue DCs gather antigen within lymphoid tissue and present antigen to T lymphocytes within the same lymphoid tissue

Examples: thymic DCs, splenic DCs

INFLAMMATORY DENDRITIC CELLS

Inflammatory DCs arise in response to inflammatory signals; they can gather antigen and present antigen to T lymphocytes and can secrete cytokines

Example: tumor necrosis factor and inducible nitric oxide synthase–producing DCs

MUCOSAL DENDRITIC CELLS

Mucosal DCs are resident in mucosal surface tissues; they can gather antigen and present antigen to T lymphocytes and help direct responses toward activation or tolerance

PREDENDRITIC CELLS

Predendritic cells can develop DC function directly in response to inflammatory stimuli

Example: plasmacytoid DCs, monocytes

Modified from Shortman K, Naik SH: Steady-state and inflammatory dendritic-cell development. Nat Rev Immunol *7:19–30, 2007.*

specific inflammatory or infectious signals and are ordinarily not identifiable in the nonchallenged state. In addition to presenting antigen, these cells secrete cytokines and other mediators, including tumor necrosis factor (TNF), that enhance host defense.

Within the conventional DC category, one can distinguish between migratory DCs and DCs that reside in lymphoid tissue. Migratory DCs fulfill the sentinel role of this leukocyte class and include LCs, dermal DCs, and interstitial DCs of other organs. Migratory DCs shuttle between end organs that interface with the external world (e.g., skin or mucosa), in the case of LCs, and regional lymph nodes. This trafficking occurs at a low level in the basal state but can be greatly enhanced in the presence of foreign antigen or inflammatory challenges.[7-10] The migratory DC takes up antigen in the periphery and, once activated, travels to regional nodes either to present antigen itself or to transfer antigen to resident DCs in the node, which then perform the presentation function to T cells. Although the molecular signals that control this migratory behavior are not understood in detail, chemokines and their receptors play a large role.[11,12] In the case of LCs, resting cells express the chemokine receptor CCR6 whose ligand, CCL20, is secreted by cutaneous keratinocytes. Upon antigen uptake and activation, LCs downregulate CCR6 and in its place upregulate another chemokine receptor, CCR7, whose ligands, CCL19 and CCL21, are secreted by cells in regional lymph nodes. This receptor switch has the dual effect of neutralizing the LC's anchor to the skin and attracting them to regional lymph nodes.

In contrast, DCs that reside in lymphoid tissue are nonmigratory. They make up most of the DCs populating the thymus and spleen and about half of the DCs in lymph nodes.[8,13] Unlike migratory DCs, which are mature when they appear in lymph nodes, resident DCs are immature, which allows them to take up, process, and present local antigens. Surface markers can distinguish several subsets of resident DCs, which are presumed to have specialized functions. In the mouse, these subsets include cluster of differentiation (CD)8+ and CD8− cells, and among the CD8− population are CD4+ and CD4− subpopulations.[14] Specific DC subsets also have characteristic gene expression profiles.[15]

LCs bear distinctive intracellular and extracellular markers that permit their distinction from DCs that reside in lymphoid tissue. The most characteristic surface marker is CD1a,[16] and the most characteristic ultrastructural feature is Birbeck granules, which are pentilaminar "tennis racket"–shaped cytoplasmic organelles that appear to be uniquely present in LCs.[17] Langerin, also known as CD207, is a cell surface marker for LCs that associates with Birbeck granules when internalized.[18] Langerin is a C-type lectin with specificity for sugars that contain mannose, suggesting that it may be involved in processing and trafficking of antigens that bear these sugars. Dectin-2 is another C-type lectin restricted to DCs,[19] and DEC-205 (CD205) is yet another lectin that is often used to identify LCs, although its expression is not as restricted to LCs as are the other lectins.[20] In the appropriate histologic context, from a diagnostic standpoint, CD1a and Langerin are the most reliable lineage-specific markers.[16]

Some authors also distinguish a group of so-called "predendritic cells" that do not ordinarily have DC functions or structure.[21,22] However, these cells can develop directly into DCs upon stimulation without the need for proliferation. One well-studied example is the plasmacytoid DC, which circulates as a nondescript mononuclear cell but acquires APC function and secretes large amounts of alpha interferon when activated.[23,24] Technically, using this definition, monocytes would also be predendritic cells. After exposure to interleukin (IL)-4 and granulocyte-macrophage colony-stimulating factor (CSF), monocytes become functional DCs, although their phenotype is closer to inflammatory DCs than conventional DCs.[25]

ORIGINS OF DENDRITIC CELLS

The availability of genetically modified mice that carry lineage-restricted markers has greatly expanded our understanding of the origins and development of DCs. Although mouse models have some limitations,[26] the major insight these animals provide is that a salient characteristic of DC ontogeny is flexibility. For example, although DCs generally have myeloid characteristics, all DC subtypes in the mouse can arise from either committed lymphoid or committed myeloid precursors.[27-29] Even though half of thymic DCs show evidence for immunoglobulin rearrangements, suggesting a lymphoid phenotype, they also transcribe the macrophage colony-stimulating factor (M-CSF) receptor gene, which is a myeloid characteristic.[30] Activation of fms-like tyrosine kinase–3 (FLT3), a growth factor receptor, is required for DC development, and it has been suggested that committed myeloid or lymphoid precursors expressing FLT3 can differentiate into DCs in the presence of FLT3 ligand.[31]

Splenic DCs have a relatively rapid turnover rate (every 3 days).[32] These cells are repopulated both by DC division and splenic precursors, as well as by bone marrow precursors. In contrast, LCs are very long-lived.[32] After their migration from the skin, the population is replenished from a pool of LC precursors in the skin, as well as by circulating monocytes.[33] The latter is dependent on the action of the chemokine CCL2 acting on its receptor CCR2.[34,35] Thus the ontogeny of LCs is distinct from that of splenic DCs. Immature DCs are more closely related to LCs but appear to be derived from noninflammatory monocytes that do not express CCR2.[36] Plasmacytoid DCs split off from conventional DCs early in development, consistent with their distinct functional characteristics.[37]

LANGERHANS CELL HISTIOCYTOSIS

The hallmark of LCH is the accumulation of LC-like DCs in one or more tissues or organs. The clinical manifestations of LCH are highly diverse. They result both from the direct, local effects of the growth and accumulation of pathologic LCs and the indirect, secondary effects these activated cells have on normal tissues, particularly cells of the immune system. Although the most commonly involved sites of disease are the bone and skin, virtually any organ or system may be involved. The pattern of involvement is not necessarily related to patterns of normal LC or DC migration.

Although the histiocytes in LCH share certain characteristics with LCs, such as expression of CD1a and the presence of Birbeck granules, recent reports suggest that mature LCs may not be the cell of origin for LCH histiocytes. In particular, a global analysis of gene expression suggested that LCH cells are more closely related to myeloid dendritic precursors than to LCs.[38] Whether this pattern of gene expression reflects a non-LC cell origin for LCH or is a consequence of LC transformation remains to be determined.

The fact that pathologic LCs are related to immunomodulatory cells and that they elicit inflammatory infiltrates suggests that LCH might be a reactive rather than a neoplastic disease. Indeed, ample precedent for this mechanism exists among the histiocytoses, including the secondary HLH syndromes that arise in the context of viral infection.[39] However, no reproducible reports exist of viral genomes recovered from LCH cells, and epidemiologic studies are not consistent with an infectious or environmental cause of LCH.[40,41,42,43] Rather, the preponderance of evidence indicates that LCH arises as a consequence of intrinsic genetic abnormalities. The most salient arguments that LCH is a neoplasm and not a reactive disease are as follows: (1) pathologic LCs are clonal, as demonstrated by nonrandom X chromosome inactivation both in whole LCH tissue (in a proportion corresponding to the proportion of CD1a+ cells in the lesion)[42] and in sorted CD1a+ cells,[44] and (2) nearly 60% of LCH samples carry the oncogenic BRAF V600E variant.[45,46] Notably, the MAPK pathway, which would be activated constitutively in the presence of BRAF V600E, is uniformly activated in LCH cells regardless of the presence or absence of BRAF V600E, suggesting that alternative mechanisms of pathway activation are present in LCH samples that lack BRAF V600E. In some cases, other activating mutations of *BRAF* have been found.[46,47] Additional known mechanisms of *BRAF* activation, such as gene amplification or translocation, which occur in other diseases, have not been described in LCH.[45] Notably, although pulmonary LCH in adults is generally considered to be a polyclonal disease, more than 40% of pulmonary LCH cases contain BRAF V600E.[45] This finding suggests that a significant proportion of these cases are clonal[48] or that multiple independently developed clones of pulmonary LCH have BRAF V600E, giving the overall appearance of polyclonality.

Although *BRAF* mutations are among the most common molecular abnormalities found in all cancers, they are not present in other histiocytoses that affect children, such as juvenile xanthogranuloma (JXG) or Rosai-Dorfman disease.[45,49] However, BRAF V600E mutations are present in the histiocytes of about 50% of patients with Erdheim-Chester disease, a rare and aggressive non-LCH of adults.[49] Furthermore, treatment of patients who have BRAF V600E–positive Erdheim-Chester disease with a *BRAF* inhibitor led to dramatic clinical responses, indicating the pathogenetic importance of this mutation.[50] Interestingly, some of these patients had concomitant LCH that also responded to *BRAF* inhibition, suggesting that this therapeutic approach may be effective in patients who have BRAF V600E–positive LCH as well.

Activating mutations of *BRAF* are insufficient by themselves to produce neoplastic disease, and therefore additional molecular alterations are likely to be required for the development of LCH. One of the most common molecular abnormalities in LCH is overexpression of *TP53*,[51] suggesting that mutational inactivation of this pathway may contribute to pathogenesis. More such changes in other genes are likely to be discovered as advanced genomic analyses are applied to LCH samples.

Incidence

The incidence of LCH is difficult to determine precisely because of the rarity and marked clinical variability of the disorder. Estimates are in the range of 2.6 to 8.9 cases per million per year for children younger than 15 years,[52-55] corresponding to roughly one tenth the incidence of acute leukemia in childhood. LCH occurs in people of all races and all ages. Although the peak age at diagnosis is 2 years, LCH can present at any time from birth to old age. No evidence of seasonal variation has been noted in the time of presentation of LCH. Several studies have shown a slight male predominance.[56,57]

No known predisposing factors exist for the development of LCH in the majority of cases.[58] Studies have demonstrated concordance of the disorder in monozygotic twins, suggesting an inherited predisposition to LCH that might account for ~1% of cases.[59] However, a positive family history is lacking in most cases. Interestingly, isolated pulmonary LCH in adults is closely linked to cigarette smoking, and it often resolves with smoking cessation.[60] However, exposure to cigarette smoke has not been linked to pediatric LCH.[61] As previously noted, a significant proportion of pulmonary LCH cases also carry the activated BRAF V600E allele.

An intriguing (although incompletely understood) association exists between malignancy and LCH. Children with a history of cancer have an increased risk of LCH. Conversely, children with a history of LCH appear to have an increased risk of cancer. This finding suggests the possibility that underlying genetic abnormalities may place individual patients at increased risk for LCH.[62] Alternatively, the association between LCH and cancer may fall within the spectrum of secondary posttherapy effects, because irradiation and drugs such as etoposide are used to treat LCH and are known to induce tumor-promoting genotoxic injury. Several cases of LCH arising in the setting of T-cell acute lymphoblastic leukemia have been described, typically when the leukemia is in remission while the patient is receiving therapy or in the early posttherapy period.[63] A clonal link between the initial leukemia and pathologic LCs of LCH has been established in some cases, suggesting that the LCH represents a manifestation of the malignant clone rather than a distinct reactive or neoplastic process related to the leukemia or its therapy.[64,65] An intriguing link may exist to hairy cell leukemia, which also harbors BRAF V600E in the majority of cases.[66]

Clinical Features

The clinical manifestations of LCH are protean. Although patterns of clinical presentation have been described, the disease is appropriately viewed as a spectrum. LCH may involve a single site, multiple sites in a single organ system, or multiple organ systems. Many patients present with localized pain, soft tissue swelling, or skin rash. Less commonly, patients have symptoms of diabetes insipidus (DI), respiratory insufficiency, cytopenias, lymphadenopathy, liver dysfunction, or organomegaly.

In the past, three distinct clinical syndromes were described: eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe disease.[67,68] "Eosinophilic granuloma," a term still commonly used by radiologists and orthopedists, refers to the presence of one or more lytic bone lesions. Hand-Schüller-Christian disease consists of the triad of bone defects, exophthalmos, and polyuria. Letterer-Siwe disease, a fulminant disorder of the reticuloendothelial system, is characterized by hepatosplenomegaly, lymphadenopathy, skin rash, bone lesions, anemia, and the tendency to bleed. This classification has important historic significance, but its applicability in the clinical setting is limited. Once it was recognized that the diverse manifestations of the disease share common histopathologic features, the three syndromes were unified under the term "histiocytosis X."[69] Categorizing patients based on the number and location of lesions and the presence or absence of organ involvement was shown to be useful in predicting prognosis and determining therapy.[70-74] Single-system LCH (SS-LCH) disease—which usually affects bone, less frequently affects skin, and rarely affects the lymph nodes, lung, or central nervous system—accounts for approximately two thirds of pediatric LCH cases. Involvement of two or more organ systems, referred to as multisystem LCH (MS-LCH), accounts for the remaining one third of cases. In about half of MS-LCH cases, "risk" organs (i.e., the liver, spleen, and hematopoietic system) are affected.[55,75] Thus far the presence of BRAF V600E does not correlate with disease extent or prognosis.

Pathology

A biopsy of lesional tissue is required to establish the diagnosis of LCH. The pathologic diagnosis is usually straightforward, but because the disease is rare, varied, and may mimic many other conditions, delay in diagnosis is common. LCH should be considered in any patient who presents with skeletal lesions, a persistent rash, chronically draining ears, central DI, unexplained lymphadenopathy, respiratory insufficiency with a reticulonodular pattern on a chest radiograph, hepatosplenomegaly, or cytopenias.

Once clinical suspicion is raised, the workup should proceed with a biopsy of the most accessible site of disease. Complete surgical excision of the lesion is generally unnecessary either for diagnosis or treatment. LCH lesions at all sites share common histopathologic features: accumulation of large neoplastic LCs with a moderate amount of dense pink cytoplasm and plump, distinctive "C-shaped," "coffee bean," or cleaved nuclei admixed with variable numbers of inflammatory cells, including T lymphocytes, macrophages, plasma cells, and eosinophils. The composition and architecture of the infiltrate characteristically differ according to the location. Osteolytic bone lesions often contain many nonneoplastic osteoclasts, as well as multinucleated tumor giant cells and large numbers of eosinophils, the latter speaking to the origin of the term "eosinophilic granuloma." Mature, "burned out" bone lesions may be difficult to distinguish from chronic osteomyelitis, which is often in the clinical and radiographic differential diagnosis. LCH infiltration of the skin typically involves the superficial dermis, with tumor cells infiltrating the epidermis (so-called "epidermotropism" or "exocytosis"), thus altering epidermal barrier function and leading to superinfection and the characteristic appearance of some LCH rashes. In all cases, the neoplastic LCs express the LC markers CD1a[16] and langerin,[76,77] as well as S100 protein[78] and fascin[79] (Fig. 64-1). Electron microscopy, which historically is used to demonstrate the presence of Birbeck granules indicative of the LC lineage, has little diagnostic utility at the present time. Cytogenetics or molecular studies are predominately needed to exclude other diseases with similar clinical presentations or histologies. Furthermore, no immunohistochemical or other laboratory methods are useful in

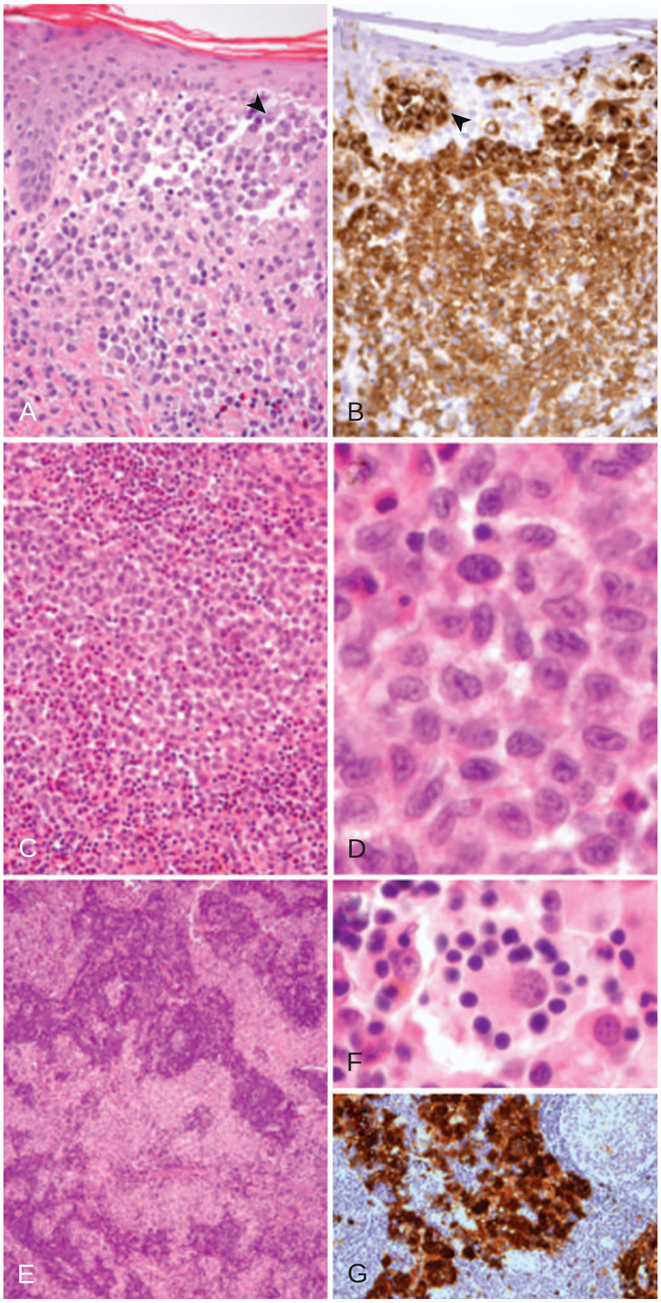

Figure 64-1 Histopathologic features of Langerhans cell histiocytosis (LCH) and sinus histiocytosis with massive lymphadenopathy (SHML). **A** and **B**, Hematoxylin and eosin (**A**) and CD1a immunostain (**B**) of LCH involving the skin. Lesional cells infiltrate the upper dermis and focally *(arrowheads)* involve the epidermis. **C** and **D**, Low-power (200× magnification, **C**) and high-power (1000× magnification, **D**) views of a hematoxylin and eosin–stained section of an LCH bone lesion. The low-power view (**C**) demonstrates tumor cells present in association with a mixed inflammatory infiltrate rich in eosinophils. The high-power view (**D**) illustrates the histologic features of the lesional Langerhans cells, including the characteristic "C-shaped" nuclei and abundant pink cytoplasm. **E, F,** and **G,** Low-power (40× magnification, **E**) and high-power (1000× magnification, **F**) views of a hematoxylin and eosin–stained section of SHML involving a lymph node. Pale areas in panel **E** represent dilated sinuses replaced by lesional histiocytes that are highlighted by an S100 immunostain in panel **G**. Panel **F** demonstrates a histiocyte that contains numerous lymphocytes, which is typical of the emperipolesis characteristic of SHML.

distinguishing clinically indolent from clinically aggressive forms of the disease.

Diagnostic Evaluation

In suspected LCH cases, evaluation for disease extent is indicated, starting with a history and physical examination.[80] A skeletal radiographic survey is recommended to comprehensively assess skeletal involvement. Abnormalities detected on plain radiographs may be followed by axial imaging to document the presence of a soft tissue mass.[81,82] Nuclear imaging (i.e., a bone scan or fluorodeoxyglucose positron emission tomography [FDG-PET]) complements the skeletal survey. Compared with plain radiographs, nuclear imaging tests detect active lesions on the basis of increased local metabolic activity. Active bone lesions usually show increased radiotracer uptake, whereas inactive lesions may be undetectable or appear "photopenic." FDG-PET appears to be the most sensitive imaging modality for the detection of lesions in persons with LCH, and it is particularly useful for following up on patients. Unlike a bone scan, PET is capable of detecting extraosseous lesions.[83-85]

Complete blood cell counts and liver function studies should be performed, and liver and spleen size should be assessed by physical examination. Abdominal ultrasound is indicated when laboratory studies are abnormal or if hepatosplenomegaly is present or suspected. The erythrocyte sedimentation rate may be elevated, but it is not a sensitive or specific disease indicator. Measurement of specific gravity of an early morning urine sample is an easy and inexpensive screening test for DI. A formal water deprivation test may be necessary to establish the diagnosis of DI. Magnetic resonance imaging (MRI) of the head should be performed in children with cranial bone lesions and when DI is suspected or confirmed. A chest radiograph should be performed in all cases, and a computed tomography (CT) scan of the chest should be performed if the radiograph findings are abnormal or if the patient has respiratory signs or symptoms. Additional evaluations such as upper/lower endoscopy and biopsies of bone marrow, skin, lymph nodes, and the liver should be considered in the appropriate clinical context.

Management

The approach to management of LCH must account for the variability in its clinical behavior. On one hand, LCH is an uncontrolled accumulation of a clonal population of cells, with the capacity to behave extremely aggressively and the potential to involve multiple sites and organ systems. The process may be driven, in part, by oncogenic variants of *BRAF*. In addition, it may be effectively treated with cytotoxic chemotherapy and radiotherapy and, based on preliminary reports, *BRAF* antagonists.[50] On the other hand, LCH is histologically benign, it sometimes resolves spontaneously, and it may respond to immunomodulatory or immunosuppressive agents. The historic uncertainty about the fundamental nature of LCH is reflected in the broad range of therapies that have been used to treat it.

Performing controlled clinical trials in persons with LCH has been challenging. As a consequence, the LCH literature is often descriptive, anecdotal, and retrospective. Since the 1980s, several collaborative groups have conducted prospective clinical trials that have led to standardization and improvements in treatment. An overall observation of these studies is that the treatment of LCH should match the clinical scenario. Patients with localized disease have an excellent prognosis with little or no intervention. For these children, the goal of therapy is to minimize symptoms and avoid long-term disability and potential late effects. In contrast, children with MS-LCH, especially those with involvement of the hematopoietic system or liver, are at significant risk for morbidity and mortality. For these children, aggressive treatment is justified.

Bone

Bone is the most commonly involved site, with bone involvement occurring in approximately 75% of children with LCH.[57] Although any bone(s) may be affected, the bones of the skull, pelvis, and vertebral bodies are most commonly affected[56] (Fig. 64-2). Bone pain (which is often worse at night), swelling, and a limp are typical presenting symptoms. Sometimes a history of local trauma precedes or coincides with the onset of symptoms. The typical plain radiographic appearance is of a smooth-edged, "punched-out" hole in the bone. Lesions of the long bones typically involve the diaphysis, but metaphyseal and epiphyseal lesions also occur. Involvement of a vertebral body may manifest as flattening or loss of height (vertebra plana) or as a wedge deformity. Axial imaging (CT and MRI) may show an associated soft tissue mass (Fig. 64-3). The radiographic differential diagnosis of osseous LCH lesions includes malignancy, especially Ewing sarcoma, leukemia or lymphoma, and osteomyelitis.

LCH of the bone may be unifocal (monostotic) or multifocal (polyostotic), and it may present in association with disease in other organ systems. Monostotic disease, which is the most common presentation of LCH (especially in older children), occurs in more than 50% of cases.[75,86] Children with LCH that is limited to a single bone have an excellent prognosis regardless of the treatment administered. Although various local and systemic therapies appear to be efficacious,[87] retrospective trials have failed to demonstrate a comparative advantage for any specific intervention or modality, including observation only, biopsy, curettage, simple excision, intralesional steroid instillation, local radiotherapy, or systemic therapy.[88,89]

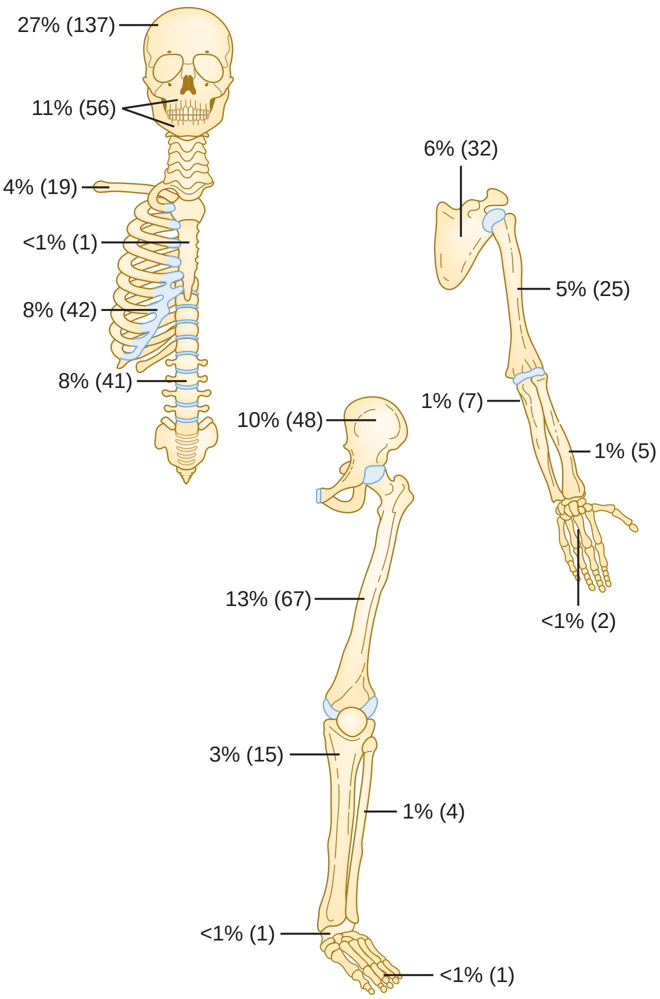

Figure 64-2 Anatomic distribution of 503 osseous lesions among 263 patients with Langerhans cell histiocytosis of bone. *(From Kilpatrick SE, Wenger DE, Gilchrist GS, et al: Langerhans' cell histiocytosis [histiocytosis X] of bone. A clinicopathologic analysis of 263 pediatric and adult cases.* Cancer *76:2471–2484, 1995.)*

Often the biopsy procedure performed to establish the diagnosis of LCH of the bone provides therapeutic benefit. In many cases, adequate tissue for diagnosis may be

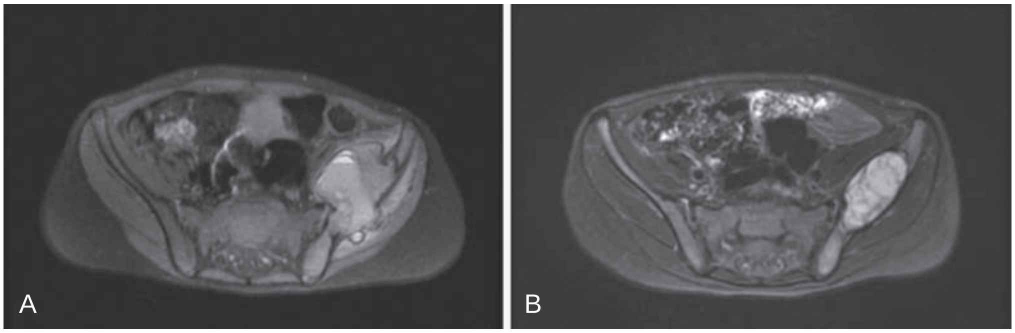

Figure 64-3 Magnetic resonance imaging scans of the pelvis of a 2-year-old boy with unifocal Langerhans cell histiocytosis of the left ilium. An expansile, destructive iliac lesion and large soft tissue mass (**A**) decreased dramatically in size within 3 months after an intralesional glucocorticoid injection (**B**).

obtained via percutaneous needle biopsy with ultrasound or CT guidance. Neurosurgeons tend to prefer open biopsy of orbital and skull base lesions and simple excision or curettage of calvarial lesions. Regardless of the surgical approach, most patients experience progressive healing after the procedure, even when complete excision of the lesion is not achieved. In cases in which LCH is strongly suspected or confirmed intraoperatively via frozen section, methylprednisolone can be instilled directly into the lesion.[90,91] This intervention yields rapid relief of pain and may hasten resolution.[92,93] Intralesional steroid injection is less commonly used in the management of cranial and vertebral lesions.

In the past, radiotherapy was routinely used to treat bone lesions. Even though a relatively low dose in the range of 600 to 1000 centigray is effective,[56,94,95] the role of radiotherapy in pediatric LCH has waned because the long-term risk of radiotherapy, especially the risk of secondary malignant neoplasms, is rarely justified in treatment of a benign disease. In the setting of disseminated disease, local radiotherapy contributes little benefit.[96]

Systemic therapy may be required for patients with monostotic LCH who experience unrelenting symptoms or are at significant risk for serious or permanent disability related to the location or extent of their lesion. This principle applies in patients with unifocal craniofacial bone involvement, including the orbit, temporal bone, mastoid, sphenoid, zygomatic, ethmoid, maxilla, paranasal sinuses, or cranial fossa (so-called "central nervous system [CNS]-risk" lesions), because these children are at increased risk for DI and other neurologic sequelae.[97] Currently it is standard practice to administer chemotherapy in "CNS-risk" cases, even though it has not been definitively established that treatment decreases the risk of neurologic complications.

Systemic therapy is also recommended for children with polyostotic (i.e., multifocal bone) LCH. In these patients, an important goal of treatment is to mitigate the risk of future reactivation,[71,75] because reactivation risk is approximately 40% for patients with multifocal bone disease versus 10% for patients with unifocal bone disease.[98] Children with SS-LCH of the bone who require systemic therapy—that is, those with CNS-risk lesions or multifocal bone involvement—are typically treated with the combination of vinblastine and prednisone (discussed later).

Skin

The skin is the second most commonly involved system in persons with LCH, with skin involvement occurring in about one third of patients.[54,55,71] Skin rashes may be extremely variable, and misdiagnosis is common. Cutaneous LCH may present as single or multiple nodules, vesicles, or scaly, seborrhea-like patches or plaques. Although the rash may be located anywhere on the body, it is typically most intense in the flexural areas, such as the neck, axillary, and inguinal folds. Involvement of the scalp, the ear canals, and the posterior auricular areas is also characteristic. Ear canal involvement may lead to chronic ear drainage that may be malodorous. Perineal and perianal rashes may be severe, persistent, and refractory to topical preparations.

Cutaneous involvement is more common in infants than in older children. Some infants with isolated cutaneous LCH prove to have a benign, self-healing disorder known as Hashimoto-Pritzker disease.[99,100] However, in infants who initially present with apparently isolated cutaneous LCH, MS-LCH may proceed to develop, and therefore self-healing cutaneous LCH is a diagnosis that can be made with accuracy only in retrospect.[101,102] The differential diagnosis of cutaneous LCH may include superficial candidiasis, seborrheic dermatitis ("cradle cap"), eczema, contact dermatitis, and viral exanthem. A skin biopsy is required to establish the diagnosis.

When treatment for cutaneous LCH is required, topical medications such as corticosteroid or nitrogen mustard may suffice.[103,104] Occasionally, systemic therapy is necessary to control extensive or severe skin involvement, especially when it is associated with pain, disfigurement, or infection. Alternatives such as psoralen ultraviolet A[105,106] or interferon[107] have been used with success in some patients who have resistant cutaneous involvement.

Central Nervous System

The brain and skull can be affected by LCH in a variety of ways, including extension of extraaxial bone-based lesions, hypothalamic-pituitary disease, intraparenchymal mass lesions, and later onset neurodegeneration.[108]

Hypothalamic-pituitary disease is the most common and best-characterized CNS manifestation of LCH. Infiltration of the pituitary stalk by lesional cells leads to deficiency of antidiuretic hormone and clinical DI.[109] Anterior pituitary deficiencies or panhypopituitarism may develop in some cases.[110] The diagnosis of DI may precede, coincide with, or occur years after the diagnosis of LCH. Estimates of the frequency of DI in persons with LCH vary considerably because of variability in study populations. One large retrospective review reported a 12% incidence of DI, with 6% having DI present at the time of LCH diagnosis. In this analysis, the risk of DI correlated significantly with the location and extent of LCH involvement. Children who have craniofacial lesions (CNS risk) or MS-LCH are at significantly higher risk for DI.[97]

Among children with a new presentation of DI, LCH is the cause in a significant proportion (approximately 15%) of cases.[111] Absence of posterior pituitary hyperintensity (the pituitary "bright spot") or thickening of the pituitary infundibulum[112] may be noted on brain imaging; however, these radiographic findings are neither sensitive nor specific for LCH. Their differential diagnosis includes brain tumors, especially germinoma, and inflammatory conditions such as hypophysitis. Investigation for other sites of LCH is worthwhile because detection and biopsy of extracranial lesions may allow histopathologic confirmation of the diagnosis without performing a pituitary stalk biopsy.[113]

Screening for DI in children who have LCH with use of a careful history is essential, and referral to an endocrinologist should be considered if symptoms of polyuria, polydipsia, nocturia, or dehydration are elicited. Urinary specific gravity greater than 1.015 weighs against a diagnosis of DI, and this reading can often be easily determined by analysis of a first-morning voided urine specimen. In cases in which the history or laboratory studies raise suspicion, a formal water deprivation test should be performed.

In general, DI is irreversible once it appears in patients with LCH. However, improvement has been reported in "early" DI cases when patients were treated promptly with chemotherapy.[114,115] At one time, emergent radiotherapy was recommended in patients with new onset DI. This recommendation has fallen out of practice because it is rarely, if ever, effective and is associated with potential long-term consequences.[116] Chemotherapy has no role in patients with established, long-standing DI who have no evidence of active LCH within or outside of the CNS.

Parenchymal CNS mass lesions in persons with LCH are composed of granulomas of CD1a+ cells admixed with other inflammatory cells. These lesions can occur in isolation or in association with disease in other organ systems. Depending on the extent and location, headaches, seizures, and focal neurologic symptoms may result. CNS mass lesions are managed with chemotherapy,[117] surgery, or radiotherapy.

Progressive neurodegeneration is an uncommon and poorly understood late event that arises years after LCH diagnosis.[118,119] Radiographically, it is characterized by signal abnormality confined to the brain stem and cerebellum on MRI.[120,121] Posterior fossa symptoms or neurocognitive dysfunction may be clinically apparent. Biopsy results show gliosis, neuronal cell loss, and lymphocytic infiltration without active CD1a+ cell infiltration.[109,122] The timing and course of this manifestation of LCH is quite variable, but it may be severe and progressive. No established treatment exists for neurodegeneration in patients with LCH. Retinoic acid[123] or low-intensity chemotherapy with or without immunoglobulin[38,124] may stabilize the disease or slow the rate of neurologic decline.

Other Sites

Lymph node involvement is occasionally present in the setting of MS-LCH, and sometimes it represents a single site of disease. The pathologic pattern of lymph node involvement is characteristically interfollicular and subtle.

The gastrointestinal tract is another uncommon site of disease in LCH, but its incidence may be underappreciated. When it does occur, it is usually in the context of multisystem involvement.[125] Clinical signs include diarrhea, bloody stools, failure to thrive, and hypoalbuminemia.[125-127] Gastrointestinal biopsies typically demonstrate a sparse infiltrate of LCs in the lamina propria.

Pulmonary involvement was historically thought to be an adverse prognostic feature, warranting its classification as a "risk" organ in early Histiocyte Society clinical trials. Involvement of the lung may be asymptomatic in up to half of affected children, with diffuse micronodular interstitial disease or cyst formation. Overt respiratory symptoms including tachypnea, chronic cough, dyspnea, and pneumothorax are seen in some patients. In children, pulmonary involvement occurs in the context of MS-LCH and is often accompanied by hematologic or hepatic dysfunction. Recent retrospective studies have shown that in the absence of other risk organ involvement, pulmonary involvement is not an independent negative prognostic indicator.[128-130] Interestingly, adults with LCH often present with disease limited to the lung, and their illness is closely linked to cigarette smoking. Cessation of smoking leads to resolution in the majority of patients.[60] Although traditionally described as a polyclonal disease, as many as 30% of cases may be clonal,[48] and a significant proportion harbor BRAF V600E.[45]

Risk Organs

Although the behavior of LCH is unpredictable, it is known that children with disease involving the hematopoietic system or liver are at highest risk for severe illness and death.[72,73] Conventionally, involvement of "risk" organs is defined by the presence of organ dysfunction, such as cytopenias, hyperbilirubinemia, and impaired hepatic synthetic function.[73] Risk organ involvement is typically a component of MS-LCH and is often associated with overt constitutional symptoms. Involvement of one or more risk organs occurs in approximately half of children with MS-LCH. Risk organ involvement is usually present at diagnosis, but it can develop later. It is clearly associated with young age, because more than half of children younger than 2 years manifest risk organ involvement. The association between young age and aggressive disease accounts for the perception that young age is an adverse prognostic feature.[53]

The presence of peripheral blood cytopenias in a patient with LCH is referred to as hematologic dysfunction and is taken to be synonymous with bone marrow involvement. Interestingly, however, evidence of bone marrow infiltration by morphologically apparent LCs is not typically seen. Most often the marrow contains a lymphohistiocytic infiltrate with hemophagocytosis that can be highly reminiscent of hemophagocytic syndromes (which will be discussed later), further illustrating that the neoplastic LCs retain some of the immunomodulatory function of their normal counterparts.[131-134] Splenomegaly is commonly seen in association with hematologic dysfunction as a consequence of organ infiltration, extramedullary hematopoiesis, and hemophagocytosis. Hypersplenism may contribute to cytopenias in these patients.

Hepatic dysfunction, like hematologic dysfunction, is associated with serious illness and a high risk of morbidity and mortality. Hepatic dysfunction is associated with any of the following findings: hepatomegaly, ascites, hyperbilirubinemia, increased serum concentrations of hepatic transaminases (especially γ-glutamyl transferase) and impaired hepatic synthetic function (hypoalbuminemia and hypoproteinemia). The pathogenesis of liver involvement is heterogeneous. In some cases hepatomegaly or transaminitis is a consequence of macrophage activation in a sinusoidal pattern in the liver and is associated with multisystem disease. In other cases, a cholestatic laboratory picture predominates, presumably resulting from the infiltration of hepatic bile ducts by CD1a+ LCs, even if these cells are not demonstrable upon a percutaneous liver biopsy.[135] In these patients, progressive hepatic dysfunction may lead over time to irreversible hepatic cirrhosis that requires liver transplantation, even after resolution of active LCH.[136]

Treatment of Multisystem LCH

Systemic therapy is indicated for all patients with MS-LCH and for some patients with SS- LCH, as previously described. The optimal therapy for this diverse group of patients is still not established. Over the years, a wide variety of immunosuppressive and cytotoxic drugs have demonstrated activity. Encouraging results were first published in the early 1960s using corticosteroids[137] and vinblastine.[138] Later, alkylating agents[139,140] and antimetabolites[141] were used. In the 1980s, the epipodophyllotoxin etoposide was shown to have particular cytotoxicity for cells of the monocyte/macrophage lineage. This agent showed promising results in children with refractory LCH and was subsequently studied in newly diagnosed patients.[142,143,144-146] More recently, the nucleoside analogs 2-chlorodeoxyadenosine (2-CdA)[147-150] and clofarabine[151,152] have shown promise in children with refractory LCH and in adults.[153] Regardless of the treatment regimen, survival among low-risk patients is excellent. However, a substantial proportion of high-risk patients still experience a progressive and fatal course despite therapy.[73,139,154,155]

The Deutsche Arbeitsgemeinschaft fur Leukamieforschung und Behandlung im Kindersalter (German Working Group for Research and Treatment of Leukemia in Childhood) performed two consecutive multicenter studies (known as DAL-HX 83 and DAL-HX 90) in which children with multifocal bone or MS-LCH were treated with a nonrandomized, risk-adapted, prospective, multidrug regimen. After initial therapy with prednisolone, vinblastine, and etoposide, children who had multisystem disease went on to receive 1 year of continuation therapy with prednisolone, vinblastine, etoposide, and mercaptopurine. In the DAL-HX 83 study, patients with organ dysfunction also received methotrexate. In these trials, approximately 67% of the patients who had organ dysfunction responded to therapy, with 42% of these patients experiencing subsequent disease reactivation. In contrast, the patients with multisystem disease who did not have organ dysfunction and the patients with multifocal bone disease had a roughly 90% response rate and a 20% reactivation rate.[71,156] Unfortunately, death due to refractory or progressive LCH occurred in about 20% of subjects in the DAL-HX studies. Mortality was restricted to children with disseminated disease, organ dysfunction, and an unfavorable response to initial therapy.

In 1991, The Histiocyte Society initiated LCH I, the first international, randomized clinical trial in persons with LCH. This study compared the efficacy of 6 months of vinblastine (arm A) versus etoposide (arm B) in children with multisystem disease.[142] The results showed that the two treatment arms, arms A and B, were equivalent in all respects, including response at week 6 (57% and 49%), toxicity (47% and 58%), probability of survival (76% and 83%), probability of disease reactivation (61% and 55%), and probability of developing permanent sequelae (39% and 51%), including DI (22% and 23%). Of the 29 children in the study who died as a result of their disease, all had risk organ involvement. The probability of survival among the children older than 2 years who did not have risk organ involvement was 100%. Secondary acute myeloid leukemia developed in one patient in arm B. In light of the fact that etoposide was not superior to vinblastine in any measure, the study suggested that the added risk associated with it may not be justified.

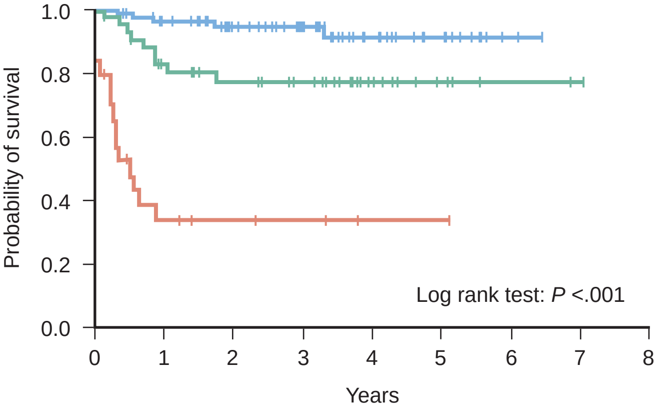

Figure 64-4 Results of the Langerhans cell histiocytosis (LCH) I clinical trial for the treatment of multisystem LCH in children. Survival related to response to treatment at week 6. The *solid line* represents responders ($n = 71/76$), the *dashed line* represents intermediate responders ($n = 32/41$), and the *dotted line* represents nonresponders ($n = 10/25$). *(From Gadner H, Grois N, Arico M, et al: A randomized trial of treatment for multisystem Langerhans' cell histiocytosis.* J Pediatr *138:728–734, 2001.)*

Importantly, analysis of the LCH I study revealed that early response to therapy is an extremely powerful prognostic indicator in persons with MS-LCH. Children younger than 2 years who had MS-LCH and failed to respond to 6 weeks of initial therapy had a dismal 17% survival rate compared with an 88% survival rate in children who responded favorably (Fig. 64-4). The prognostic value of early response was confirmed in a retrospective analysis of the DAL-HX 83 and DAL-HX 90 studies.[157]

The Histiocyte Society's successor study, LCH II, intensified treatment for all patients and further explored the role of etoposide in persons with MS-LCH. All children received 6 weeks of initial therapy that consisted of continuous oral prednisone and weekly administration of vinblastine. Low-risk children who were risk organ negative received continuation therapy with pulse prednisone and vinblastine every 3 weeks for a total of 6 months. High-risk children who were risk organ positive also received mercaptopurine and were randomly assigned to either receive etoposide (arm B) or not receive etoposide (arm A) during both the initial and continuation phases. LCH II did not demonstrate a statistically significant benefit of the addition of etoposide in patients with MS-LCH; response at week 6 (63% vs. 71%), survival (74% vs. 79%), disease reactivation (46% in both arms) and permanent consequences (43% vs. 37%) were all similar in arms A and B, respectively. However, in comparison with the less-intensive therapy studied in the LCH I trial, the more intensive LCH II regimen did show a somewhat higher rapid response rate and lower mortality in children with risk organ involvement.[158]

LCH III opened for enrollment in 2001. For the highest risk group of subjects in this study—that is, the children with MS-LCH who had involvement of risk organs—methotrexate was added to the backbone of prednisone, vinblastine, and mercaptopurine in a randomized fashion. The total duration of therapy was lengthened to 12 months for all high-risk patients. Children without risk organ involvement were randomly assigned to receive vinblastine and prednisone for 6 versus 12 months. The study failed to demonstrate a benefit as a result of the addition of methotrexate to the standard backbone in multisystem high-risk patients. However, prolongation of therapy from 6 to 12 months in multisystem low-risk patients is associated with a significantly lower reactivation rate (a 3-year cumulative incidence of reactivation of 50% vs. 35%).[159]

Refractory Langerhans Cell Histiocytosis

Children with MS-LCH whose disease does not respond promptly to vinblastine and prednisone have an unfavorable prognosis, with survival rates in the range of 10% to 34%.[142,156] Unfortunately, LCH that is resistant to vinblastine and corticosteroid is often unresponsive to other conventional agents. 2-CdA, a nucleoside analog, has shown significant promise as salvage therapy in children with reactivated or refractory disease.[147,160,161] Dramatic responses to 2-CdA combined with cytarabine have been observed in children with refractory LCH who have hematologic dysfunction.[150] Also, the nucleoside analog clofarabine has demonstrated activity in a smaller number of reported cases of refractory MS-LCH.[151,152]

A small but growing number of children with refractory MS-LCH have been successfully treated with allogeneic hematopoietic cell transplantation (HCT).[162-166] Not surprisingly, toxicity is a significant obstacle in these very ill patients. Autologous transplantation has not resulted in durable responses.[167] Transplant regimens that incorporate reduced intensity conditioning are especially appealing in persons with refractory LCH and appear to be feasible, with lower transplant-related morbidity and mortality.[168,169]

Reactivation

Some children experience LCH reactivation after initial improvement or resolution of their disease. Most reactivations occur within 1 year of diagnosis, and almost all develop within 2 years.[75,170] Patients with MS-LCH are clearly at higher risk of reactivation than are patients with SS-LCH. Patients occasionally experience a chronic, relapsing, and remitting course with repeated reactivations. Aggressive radiographic surveillance for reactivation is generally discouraged, because the site of reactivation is unpredictable and the risk of imaging may outweigh the benefit of early diagnosis. However, monitoring physical examination and growth and development is advised, along with prompt evaluation of any new signs or symptoms. Elevation of the erythrocyte sedimentation rate and the platelet count can be a tip-off to disease reactivation.[171]

Bone is the most frequent site of LCH reactivation. Fortunately, reactivation in risk organs is distinctly uncommon in children who did not have risk organ involvement at presentation.[172] Localized reactivations, such as a single bony site or recurrent rash, may be effectively managed with local therapy alone (i.e., surgery or intralesional or topical administration of a corticosteroid). However, systemic therapy is often necessary in persons with reactivated disease to control symptoms, prevent permanent sequelae, and decrease the severity and frequency of subsequent reactivations. In contrast to recurrent malignancies in which acquired drug resistance limits the efficacy of cytotoxic drugs after previous exposure, in reactivated cases of LCH, medications used successfully in the setting of newly diagnosed disease often remain effective in the treatment of reactivation. When cytotoxic therapies such as corticosteroids, vinca alkaloids, antimetabolites, or nucleoside analogues fail to provide durable disease control or when adverse effects are limiting, more intensive and less conventional options are worth exploring. For these relatively rare cases, therapy must be individualized, keeping in mind the specific site(s), symptoms, and risk of the reactivation, as well as the specific adverse effects of therapy.

Alternatives to conventional therapy that have been used in bone reactivation include nonsteroidal antiinflammatory agents (e.g., indomethacin)[106] and bisphosphonates (e.g., pamidronate).[173,174] These agents may act to ameliorate pain but may not directly inhibit disease activity. Thalidomide has shown some efficacy in patients with low-risk LCH that is refractory to conventional therapy. The presumed mechanism of action is by inhibition of TNF or other cytokines.[175] Many children who undergo repeated reactivations experience permanent disabilities related to their LCH. Nonetheless, their overall likelihood of survival approaches 100%.[76]

Long-Term Consequences

Roughly half of survivors of LCH experience irreversible long-term consequences of their illness or, to a lesser extent, of the therapy they received. The incidence and pattern of sequelae strongly correlate with the initial extent and pattern of disease involvement; patients who experience multisystem disease and multiple reactivations are at highest risk.[170,176,177] A considerable fraction of irreversible complications observed in survivors of LCH were present at the time of diagnosis, and thus not all long-term complications are preventable.

Orthopedic complications are the most frequently observed permanent sequelae in survivors of SS-LCH. Examples include spinal deformity leading to scoliosis or kyphosis, dental loss due to involvement of the jaw, and facial asymmetry or proptosis due to involvement of orbital or facial bones. Although conductive hearing loss attributed to chronic inflammation of the middle and external ear is reversible, sensorineural hearing loss due to involvement of osseous structures is usually permanent when it occurs. Although permanent orthopedic and cosmetic consequences are relatively frequent, they do not necessarily adversely affect the quality of survival.[76]

DI is an irreversible condition in almost all cases in which it occurs, and a lifelong need for desmopressin is to be expected. Similarly, other endocrinopathies such as growth hormone deficiency and panhypopituitarism are not responsive to LCH-directed therapy but are managed with hormone supplementation. Awareness and close attention to growth and development are very important in the follow-up care of these patients.[97]

Rarely, survivors of LCH experience progressive end organ damage in the absence of demonstrable activity of LCs. Progressive hepatic cirrhosis with liver failure requiring liver transplantation is a rare but well-recognized late event.[136] A somewhat analogous process may occur in the lungs, leading to pulmonary fibrosis, cystic changes, or spontaneous pneumothorax. Adult survivors of pediatric LCH should be counseled to avoid exposure to cigarette smoke because of the potentially increased risk of developing pulmonary abnormalities.[178] Neurodegeneration, which was previously described, is the most dreaded late event in survivors of LCH.

Overview of Therapeutic Options

Approach to SS-LCH

Children with localized SS-LCH have an excellent prognosis. Most children with localized disease may be safely observed after a biopsy or resection is performed, without the need for additional intervention. Local therapy may be added to accelerate resolution of symptoms. In patients with craniofacial bone or multifocal bone disease or isolated CNS involvement, systemic therapy is indicated to control symptoms and to prevent reactivations and long-term (especially orthopedic and neuroendocrine) sequelae.

Approach to Low-Risk MS-LCH

Children with MS-LCH who do not have involvement of risk organs have an excellent prognosis. Because their course is generally favorable, maximizing response while minimizing short- and long-term toxicities is the primary objective. When possible, enrollment in a clinical trial is encouraged. The current standard of care in the United States is the combination of vinblastine and prednisone for a total duration of 12 months.

Approach to High-Risk MS-LCH

Thus far, up-front intensification of therapy has not been shown to improve outcome in children with MS-LCH who have involvement of risk organs. Children with high-risk features who respond favorably to standard chemotherapy have a good prognosis, but children who do not respond rapidly to standard treatment have a poor prognosis. For this group of patients, intensive chemotherapy, investigational agents, or HCT should be considered.

The role of *BRAF* inhibitors in patients whose LCH cells harbor oncogenic *BRAF* variants remains to be established. The increased risk of squamous cell carcinomas of the skin associated with the currently available inhibitors will likely restrict their use to patients with a poor prognosis in whom the benefits may outweigh the risks.

NON–LANGERHANS CELL HISTIOCYTOSES

In addition to LCH, a spectrum of other even rarer histiocytic lesions exists that affect both children and adults. In general they include a large number of clinically benign, not infrequently progressive dermatologic disorders that are pathologically characterized by proliferations of Langerhans-like cells, often with distinctive cytosolic features[179,180] (see Fig. 64-1). Other rare non-LCHs, most notably Erdheim-Chester disease and the “true” malignancies such as Langerhans cell sarcoma and histiocytic sarcoma,[181] have high mortality rates. With the exception of JXG and sinus histiocytosis with massive lymphadenopathy (SHML), these disorders will not be discussed further because of their rarity, and the reader is referred to several authoritative reviews on these diseases.[179,180]

Juvenile Xanthogranuloma

JXG is a generally benign tumoral proliferation of histiocytes with a CD1a–, S100–, Langerin–, CD68+, CD163+, fascin+ immunophenotype that, like LCH, is believed to be derived from dermal interstitial DCs. Lesions characteristically present as reddish to yellowish-brown cutaneous nodules in the head and neck region of children younger than 1 year of age; the median age of onset is 5 months, and tumors may be congenital. Multifocality is not uncommon, particularly in male infants.[180,182] An association exists with neurofibromatosis 1, Noonan syndrome, and juvenile myelomonocytic leukemia.[183] The natural history of most lesions is spontaneous regression, but they are often diagnosed by excisional biopsy, leaving little or no residual tumor. Extranodal involvement of the deep soft tissues, liver, spleen, conjunctivae, and the CNS—so-called systemic JXG—with or without cutaneous involvement occurs in nearly 5% of cases.[182,184] Although systemic lesions also typically regress, local disease, as in the eye and CNS, may lead to significant morbidity. Patients with systemic disease involving the CNS or liver have occasionally died of their disease.[182,184,185] In cases requiring treatment, single agents[186,187] or multiagent regimens similar to those used for persons with LCH have been employed with success.[188]

Sinus Histiocytosis with Massive Lymphadenopathy

SHML, also known by the eponym Rosai-Dorfman disease,[189] is an enigmatic histiocytic disorder associated with a proliferation of CD1a–, Langerin–, S100+, CD68+, CD163+, fascin+ histiocytes with abundant foamy cytoplasm.[180] Most characteristically, a subset of lesional histiocytes contains a large number of lymphocytes and other cells, but unlike in the hemophagocytic syndromes (discussed later), these cells are not contained within phagolysosomes. Rather, they are “just passing through” in invaginations of the cell membrane, in a process termed *emperipolesis*[190] (see Fig. 64-1). In lymph nodes, these histiocytes preferentially involve the nodal sinuses and secondarily the interfollicular areas, leading to remarkably huge lymphadenopathy, which gives the disease its name.

Because the SHML literature is largely retrospective, particularly since 1990 when a patient registry was last updated,[191] the reported patterns of clinical presentation and natural history of the disease are undoubtedly biased. Nevertheless, the prototypical clinical presentation is massive, painless cervical lymphadenopathy. In addition, up to 40% of patients present with extranodal disease, most commonly in the skin, upper respiratory tract, and bone.[191] The orbit and meninges are also not uncommon extranodal sites.[192,193] Although extensive nodal and extranodal (especially kidney, lower airway, and liver) disease and coexisting immunologic disorders tend to correlate with an adverse prognosis, it is apparent that many if not most cases remit spontaneously without therapy.[191,194,195] Constitutional symptoms including fever associated with neutrophilia, increased erythrocyte sedimentation rate, and polyclonal hypergammaglobulinemia that are often associated with SHML usually respond to systemic corticosteroids. In cases in which disease has compromised organ function, requiring therapy, no treatment modality is clearly preferred; surgical debulking and radiation therapy generally result in some amelioration, but the response to systemic chemotherapy—often a combination of alkylators, vinca alkaloids, and steroids—is inconsistent.[191,196]

MONOCYTES AND MACROPHAGES

Resident tissue macrophages play essential roles in host defense, especially when they populate tissues that face the external environment (e.g., alveolar macrophages in the lung). However, macrophages also contribute to tissue homeostasis through their repair and clearance activities. Functional and morphologic heterogeneity among macrophages has been long recognized, and identification of specific subsets has been aided by antibody-based identification of characteristic cell surface markers.[197] Some of these subsets may be involved in the histiocytoses of macrophage origin.

Among the macrophages active in host defense and inflammation, alveolar and gut macrophages are best understood. These cells express pattern recognition receptors and scavenger receptors that enhance recognition of microbial products,[198] are highly phagocytic, and are efficient antigen presenters. However, even within this category some degree of heterogeneity exists because gut macrophages tend to secrete lower amounts of proinflammatory cytokines. Kupffer cells are derived from macrophages and may also play a primarily defensive role in the host. In contrast, macrophages involved in homeostasis include osteoclasts and microglia.

Macrophages in secondary lymphoid organs show additional degrees of heterogeneity, with specific cell types occupying characteristic anatomic niches.[198,199] In the spleen, red pulp macrophages, which express high levels of the murine surface marker F4/80, are distinguishable from tingible body macrophages in the white pulp. Also present in the white pulp are metallophilic macrophages, which align adjacent to the marginal sinus.[200] Within the marginal zone itself are functionally distinct macrophages that express pattern recognition and scavenger receptors they may use to clear pathogens from the bloodstream.[201-203] These macrophages express much lower levels of the F4/80 marker than do red pulp macrophages. Similar subanatomic heterogeneity is observed in lymph nodes: macrophages in cortical regions express low levels of F4/80, whereas macrophages in the medullary sinuses, paracortex, and subcapsular sinuses express high levels of F4/80.[204]

In the absence of specific stimuli, tissue macrophages remain in a low-functioning, resting state. Activation induces functions that are characteristic of their host protection or homeostasis roles. Based on in vitro analyses, four distinct pathways of macrophage activation have been described.[205-207] "Classical" activation via interferon-γ or lipopolysaccharide induces microbicidal activities and upregulation of major histocompatibility complex class II expression. "Alternative" activation via IL-4 or IL-13 induces expression of genes that are involved in tissue repair or suppression of inflammation. "Innate" activation via toll-like receptor ligands also induces microbicidal activities. Finally, "deactivation" via IL-10 or transforming growth factor–β stimulation reduces class II expression and increases secretion of antiinflammatory cytokines. As clearly defined as these pathways are in vitro, little evidence exists as yet that they are relevant in vivo. However, secretion of cytokines by activated macrophage-derived cells may be a major pathophysiologic factor in histiocytoses.[208] The first and third mechanisms lead to the production of what are sometimes called "M1" macrophages, whereas the second and fourth mechanisms produce "M2" macrophages.[209]

Origins of Macrophages

For the most part, steady-state renewal of tissue macrophages appears to be accomplished by local proliferation of similar cell types. However, under conditions of rapid turnover such as inflammatory states, macrophages are replaced by bone marrow precursors—that is, circulating monocytes.[210] Recent findings have revealed substantial heterogeneity among circulating monocytes and the roles played by specific subsets in macrophage development.

Broadly defined, circulating monocytes can be separated into "classical" or inflammatory cells versus "resident" cells, which have a phenotype that closely resembles tissue macrophages.[197,211] Cell surface markers can distinguish these subsets: inflammatory monocytes are CD14hi CD16− in humans and Ly6C+ in mice; resident monocytes are CD14+ CD16+ in humans and Ly6C− in mice. Experiments in mice have tracked the fate of some of these cells.[212] For example, bone marrow–derived Ly6C+ cells, which express high levels of the chemokine receptor CCR2 and low levels of the chemokine receptor CX3CR1, enter the circulation. Ordinarily, these cells are very short-lived, but in inflammatory states, they are attracted to affected sites where they can differentiate into macrophages or DCs. Meanwhile, the precise process whereby circulating monocytes replenish resident macrophages (which are CCR2−, CX3CR1hi, Ly6C−) is unknown. Nonetheless, some of the signals that dictate tissue-specific macrophage differentiation are understood. For example, circulating mononuclear precursors that localize to bone will become osteoclasts under the influence of m-CSF and receptor activator of nuclear factor kappa-B ligand,[213] which may have pathophysiologic relevance in histiocytic disorders that attack bone.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

HLH is not a single disease entity but rather a syndrome consisting of clinical signs and laboratory abnormalities that result from the uncontrolled proliferation and activation of cells of the monocyte/macrophage lineage. Normally, monocytes and macrophages are responsible for phagocytosis of antigen and activation of other immune cells through the production of cytokines and chemokines. By way of their interactions with natural killer (NK) cells, macrophages are an important feature of the innate immune response. Additionally, they participate in adaptive immunity via their complex interactions with T cells. When pathogens, especially viral pathogens, are not rapidly eliminated by the innate immune response, the chemokines and cytokines produced by activated macrophages stimulate and perpetuate T-lymphocyte activation. Activated macrophages are themselves regulated by stimulatory and inhibitory factors that they and other immune cells produce. When this complex process escapes control, extremely potent and destructive inflammatory forces are unleashed. Uncontrolled macrophage activity is the hallmark of HLH. Although the pathogenetic mechanisms underlying the hyperinflammatory state in HLH are heterogeneous, the clinical consequences are shared.

The earliest published reports of hemophagocytic syndrome by Farquhar described four siblings who were afflicted in early infancy with fever, irritability, hepatosplenomegaly, and pancytopenia. Autopsy demonstrated histiocytic proliferation throughout the reticuloendothelial system with prominent hemophagocytosis.[214,215] The disorder was dubbed "familial haemophagocytic reticulosis" and was recognized as distinct from Letterer-Siwe disease (i.e., the disseminated form of LCH).[216] An autosomal-recessive pattern of inheritance was proposed. Subsequently, sporadic cases with similar clinical features were seen in association with viral infections,[217] bacterial infections,[218] and a host of other infections.[219] Concomitantly, it was observed that certain systemic illnesses, notably rheumatologic conditions and malignancies, occasionally led to the development of clinical features of hemophagocytic syndrome. In 1987, the Histiocyte Society adopted the unifying term *hemophagocytic lymphohistiocytosis* and defined a set of diagnostic criteria to assist clinicians and researchers. The criteria have subsequently been refined to account for advances in our understanding of the syndrome[220,221] (Box 64-2).

Incidence

HLH is broadly categorized into two forms: familial (FHL) and secondary (sHLH). Undoubtedly the delineation is an oversimplification, because significant clinical and perhaps even genetic overlap exists between the two forms. Importantly, FHL and sHLH may be indistinguishable at presentation.

Box 64-2 Diagnostic Guidelines

DIAGNOSTIC GUIDELINES (1994)*

CLINICAL CRITERIA

- Fever
- Splenomegaly

LABORATORY CRITERIA

- Cytopenias (hemoglobin <9 g/L; platelets <100 × 109/L; neutrophils <1.0 × 109/L)
- Hypertriglyceridemia and/or hypofibrinogenemia (fasting triglycerides ≥3 SD, fibrinogen ≤3 SD of normal for age)

HISTOPATHOLOGIC CRITERIA

- Hemophagocytosis in marrow, spleen, or lymph nodes
- No evidence of malignancy

REVISED DIAGNOSTIC GUIDELINES (2004)

Molecular diagnosis consistent with hemophagocytic lymphohistiocytosis OR five of the following eight clinical, laboratory, and histopathologic criteria

CLINICAL CRITERIA

- Fever
- Splenomegaly

LABORATORY CRITERIA

- Cytopenias (hemoglobin <9 g/L; platelets <100 × 109/L; neutrophils <1.0 × 109/L)
- Hypertriglyceridemia or hypofibrinogenemia (fasting triglycerides ≥3 standard deviations, fibrinogen ≤3 standard deviations of normal for age)
- Hyperferritinemia (>500 µg/L)
- Elevated CD25 (≥2400 U/L)
- Low/absent natural killer function

HISTOPATHOLOGIC CRITERIA

- Hemophagocytosis in marrow, spleen, or lymph nodes with no evidence of malignancy

Data from Henter JI, Horne A, Arico M, et al: HLH-2004: diagnostic and therapeutic guidelines for hemophagocytic lymphohistiocytosis. Pediatr Blood Cancer *48:124–131, 2007; and Henter JI, Elinder G, Ost A: Diagnostic guidelines for hemophagocytic lymphohistiocytosis. The FHL Study Group of the Histiocyte Society.* Semin Oncol *18:29–33, 1991.*

*All criteria required. If hemophagocytic activity is not proven at presentation, further search is encouraged.

In persons with FHL, an ordinary immune stimulus, such as a common viral exposure, triggers an unrestrained hyperinflammatory state as a result of the existence of an inherited, intrinsic defect in the patient's immunologic effector function. FHL is genetically heterogeneous, resulting from mutations that disturb the function of one or more of several proteins that participate in lymphocyte cytotoxicity. Approximately 1 in 50,000 live births are estimated to be affected by FHL.[222] A slight preponderance of males may be attributable to the occurrence of FHL in association with X-linked lymphoproliferative disorders.

In contrast, sHLH develops as a consequence of an intense immunologic stimulus in the form of an infection, malignancy, or inflammatory process in a person without an inherited immune defect. sHLH is more prevalent than

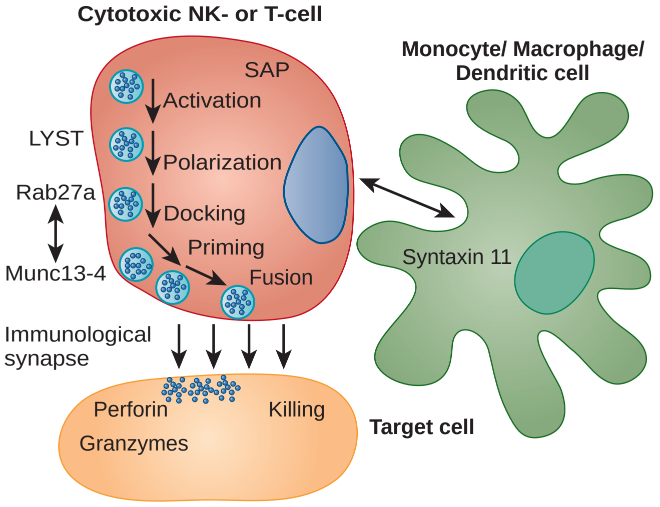

Figure 64-5 Mechanics of cytotoxic function revealed by hemophagocytic lymphohistiocytosis (HLH)-associated gene mutations. HLH-associated genetic abnormalities (in the indicated genes) may affect granule-dependent lymphocyte cytotoxicity by impairing trafficking, docking, priming for exocytosis, or membrane fusion of cytolytic granules. The function of this pathway may also be severely impaired by loss of functional perforin, the key delivery molecule for proapoptotic granzymes. Diverse mutations in this pathway all give rise to similar clinical phenotypes (albeit of variable severity). *LYST* (the gene affected in Chédiak-Higashi syndrome) is not portrayed because its function is not entirely clear, although it appears to play an important role in the maintenance of normally sized (and functional) cytolytic granules. *(From Jordan MB, Allen CE, Weitzman S, et al: How I treat hemophagocytic lymphohistiocytosis.* Blood *118:4041–4052, 2011.)*

FHL,[223] but its true incidence in children and adults is not defined.

Clinical Features

The cardinal clinical features of HLH are persistent high fever, cytopenias, and splenomegaly, with or without hepatomegaly. Unquestionably, this constellation of signs and symptoms is not rare or specific. Furthermore, establishing the diagnosis is made more difficult by the fact that all clinical features of the disorder may not be initially or simultaneously present (Fig. 64-5).

Persistent and prolonged fever is essentially universal and is usually the first sign of illness. Signs of a routine childhood upper respiratory or gastrointestinal illness often accompany the fever. However, instead of resolving in the typical time course, constitutional symptoms generally progress in children who have HLH. At presentation, affected patients are usually acutely ill and require urgent evaluation and intervention.

Cytopenias that affect at least two cell lines are a key feature of HLH. Thrombocytopenia is almost always present. The platelet count may be normal or mildly depressed initially, but it often falls precipitously as the disease progresses. Normocytic anemia with reticulocytopenia is also common. In cytopenic patients, less than the expected increment may be seen in response to transfusions because of shortened survival of transfused blood cells. Leukopenia and neutropenia are more variably present.

Abdominal distention and hepatosplenomegaly are usually present and may be accompanied by jaundice and ascites. Biochemical evidence of liver dysfunction is typical, although it is not a universal feature of HLH. Hypertriglyceridemia,[224,225] increased transaminases, or hyperbilirubinemia may be present and may in a very young child raise the possibility of primary liver disease or a metabolic disorder. Impaired hepatic synthetic function and clotting factor consumption leads to hypofibrinogenemia and prolongation of the prothrombin and partial thromboplastin times. When coagulopathy is combined with thrombocytopenia, the risk of bleeding escalates.[226] Spontaneous hemorrhage, especially intracranially, may lead to acute decompensation and may raise an erroneous suspicion of child abuse.[227]

Typically, the serum ferritin level is markedly elevated in patients who have active HLH.[228,229] A serum ferritin level exceeding 10,000 μg/L is a highly sensitive and specific marker that supports the diagnosis.[230,231] However, although most patients with HLH have an increased ferritin level, not all patients demonstrate extreme hyperferritinemia. Furthermore, mild to moderate elevation in the serum ferritin level may be seen in disorders other than HLH, such as inflammatory conditions, infections, liver disease, hemochromatosis, and metabolic disorders. The precise mechanism of ferritin elevation in persons with HLH is unknown, but it is probably related both to increased synthesis of ferritin mediated by high levels of cytokines[232] and increased release of ferritin due to liver injury and red blood cell turnover.

In keeping with a state of generalized, uncontrolled inflammation, the levels of various cytokines are increased in patients with active HLH, including IL-2, IL-6, IL-8, IL-10, interferon, and TNF.[233-235] Cytokine levels are not routinely measured, but the soluble IL-2 receptor (also known as CD25) is available as a clinical laboratory test. CD25 elevation is a sensitive and reliable marker of HLH activity,[236] and it has been incorporated into the diagnostic criteria for HLH.[220] CD25 levels are also elevated in other disorders, especially lymphoid malignancies, but typically to a lesser degree.

The term *hemophagocytosis* describes the pathologic finding of activated, histologically benign macrophages engulfing erythrocytes, leukocytes, platelets, and their precursor cells (Fig. 64-6). This process is often assessed in the bone marrow, but it occurs throughout the reticuloendothelial system (i.e., in the liver, spleen, and lymph nodes) and sometimes in the CNS. Destruction of blood cells and their precursors leads to peripheral blood cytopenia(s), often in association with bone marrow hypercellularity. Analysis of the bone marrow is always recommended when a diagnosis of HLH is suspected, both to demonstrate hemophagocytosis and to rule out the presence of leukemia/lymphoma. Although the finding of hemophagocytosis in the bone marrow supports the diagnosis of HLH in the proper clinical context, it is not essential for the diagnosis or pathognomonic. In a series of 122 children with HLH from the Histiocyte Society's International Registry, only 75% had evidence of hemophagocytosis at diagnosis.[237] In some cases, repeated bone marrow analyses may be necessary to document hemophagocytosis. Neither the pathophysiologic basis for hemophagocytosis nor its precise mechanism is well

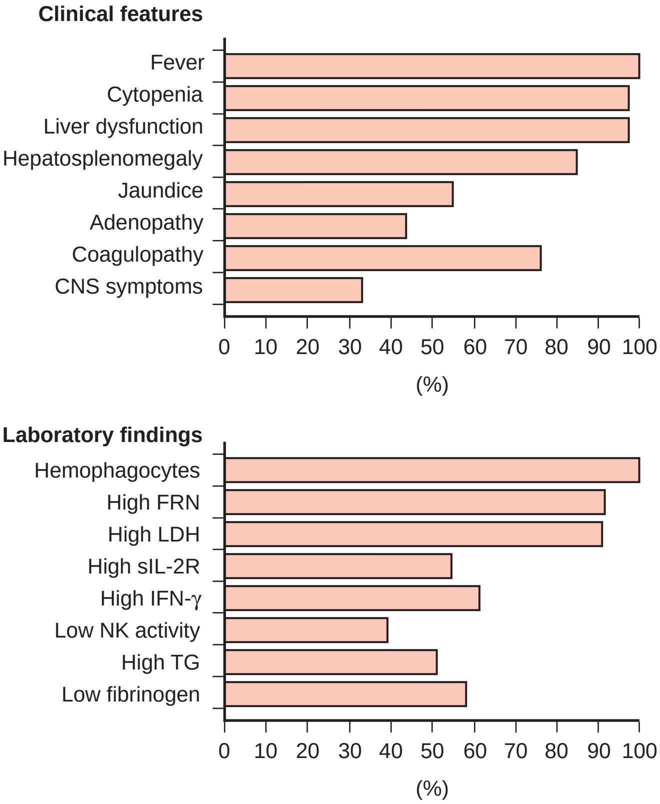

Figure 64-6 Incidence of clinical features and abnormal laboratory findings in 82 cases of hemophagocytic lymphohistiocytosis. *CNS,* Central nervous system; *FRN,* ferritin (normal range 8 to 78 μg/L); *IFN-γ,* interferon gamma; *LDH,* lactate dehydrogenase (normal range, 234 to 471 IU/L); *NK,* natural killer; *sIL-2R,* CD25 (normal range, <1090 U/mL); *TG,* triglycerides.[328]

understood. In HLH, hemophagocytosis is a reactive process that presumably results from the dysregulated immune response.

Despite the hyperactivity of the immune response in HLH and the presence of normal numbers of effector cells in many cases, targeted killing by these cells is depressed or absent. In the laboratory, impaired effector function may be demonstrated with use of a standard chromium release assay against K562 target cells. In the setting of active HLH of any variety, the functional activity of NK cells is usually impaired.[238] Manipulation of the conditions of the NK cell functional assay by the addition of mitogen or IL-2 or prolonged incubation times results in restoration of NK cell function in some patient samples.[239] It appears that the inability to reconstitute NK functional activity in vitro using modified assay conditions is associated with the familial form of the disease.[240] Some degree of correlation exists between the pattern of NK functional impairment and the molecular abnormality present in patients with FHL.[241,242]

Normally, when stimulated cytotoxic T cells and NK cells undergo exocytosis of lytic granules, expression of CD107a is induced on the cell surface, where it can be detected by flow cytometry. In a very high proportion of patients with most forms of FHL, CD107a degranulation is abnormal. Importantly, however, the assay is normal in the majority of patients with sHLH and in patients with FHL that is related to perforin deficiency (FHL2) and XLP. The CD107a degranulation assay, combined with flow cytometry for perforin and SAP and XIAP in males, may allow for rapid identification of patients with FHL.[243]

Evaluation for infectious agents should be undertaken as part of the initial workup in patients with the clinical features of HLH. Bacterial cultures and tests for other pathogens such as Epstein-Barr virus (EBV), cytomegalovirus, herpes simplex virus, respiratory syncytial virus, adenovirus, fungi, and protozoa should be performed on the basis of the patient's symptoms and exposure history. Identifying and treating infection when possible is a very important part of managing the condition of these critically ill patients. However, evidence of a bacterial, viral, or other infection in a patient with HLH does not discriminate between the familial and acquired forms of the disease. In fact, patients with FHL commonly present after an identifiable infectious trigger.[237] Conversely, a specific infectious trigger may not be identified in all patients who turn out to have infection-associated hemophagocytic syndrome. The possibility of a secondary infection must be assessed and managed conservatively in these patients, who are likely to be febrile and neutropenic and may be hemodynamically unstable.

A range of CNS symptoms including irritability, lethargy, seizures, and focal deficits may be seen. Analysis of the CSF may show pleocytosis (especially with activated monocytes present) or elevated CSF protein. Evidence of hemophagocytosis is present in a minority of cases. MRI of the brain may demonstrate a wide range of abnormalities.[244,245] CNS manifestations including neurologic symptoms, abnormal CSF, or both are reported in up to 63% of children at diagnosis,[246] and they develop in most if not all cases of advanced FHL.[247,248] Occasionally, neurologic symptoms represent the most conspicuous manifestation of illness, obscuring and delaying the correct diagnosis of HLH.[249] Pathologically, CNS involvement is variable, with meningeal inflammation at the mild end and multifocal brain infiltration with necrosis at the severe end of the clinical spectrum.[250] CNS involvement occurs in both FHL and sHLH.[251]

Familial Hemophagocytic Lymphohistiocytosis

FHL is predominantly a disease of early childhood. Although congenital cases do occur, most affected infants are born healthy and grow normally until the onset of symptoms in the first few months of life, often in association with an otherwise routine childhood infection. The peak age at diagnosis is 1 to 6 months, and it is estimated that approximately 70% are diagnosed within the first year of life. However, the age range at diagnosis is wide. FHL has been reported in patients beyond the fourth decade of life.[252-254]

As previously described, familial inheritance was recognized in the earliest descriptions of the clinical phenotype, and an autosomal-recessive pattern of inheritance

TABLE 64-1 Familial Hemophagocytic Lymphohistiocytosis Genes

Disease	Locus	Gene	Gene Symbol	Syndromic Associations
FHL1	9q22.1-23	Unknown	Unknown	None
FHL2	10q22	Perforin	*PRF1*	None
FHL3	17q25	Mammalian homologue of *Caenorhabditis elegans* (Unc13)	*UNC13D*	None
FHL4	6q24	Syntaxin-11	*STX11*	None
FHL5	19p13	Syntaxin binding protein 2	*STXBP2*	None
Griscelli syndrome type 2	15q21	RAS-associated protein (RAB27A)	*RAB27A*	Hypopigmentation, +/– neurodegeneration
Lysinuric protein intolerance	14q11.2	Solute carrier family 7, member 7	*SLC7A7*	Protein intolerance, malabsorption, failure to thrive
Chédiak-Higashi syndrome	1q42.1-42.2	Lysosomal trafficking regulator	*LYST*	Partial albinism, giant lysosomes/melanosomes, neutropenia, susceptibility to infection
XLP1	Xq25	Signaling lymphocyte activation molecule (SLAM)-associated protein (SAP)	*SH2D1A*	Sensitivity to Epstein-Barr virus infection, hypogammaglobulinemia, lymphoma
XLP2	Xq25	X-linked inhibitor of apoptosis	*XIAP*	Splenomegaly, hypogammaglobulinemia

was inferred for many cases.[255] It is evident that the familial forms of HLH can be subdivided into nonsyndromic forms, in which the only or predominant clinical phenotype is a predisposition to hemophagocytic syndrome, and syndromic forms, in which hemophagocytosis is only one, often inconstant phenotype present in association with other systemic abnormalities, particularly pigmentation defects or immune deficiency (Table 64-1).

Early on, genetic linkage studies performed with large nonsyndromic FHL families indicated substantial genetic heterogeneity with potential linkage to several different loci, systematically named FHL1 to FHL5. FHL1, which was among the first to be mapped, continues to defy molecular characterization.[256] However, the genes responsible for FHL2, FHL3, FHL4, and FHL5 have been cloned and have led to remarkable insights into the pathogenesis of this group of disorders. Each encodes a component required for development or trafficking of a mature, fully capacitated cytotoxic lymphocyte or NK cell cytotoxic granule.

FHL2 is due to mutations in the gene that encodes perforin (*PRF1*).[257,258] Perforin is a component of T-lymphocyte and NK cell cytotoxic granules that is homologous to the pore-forming complement component C9, and like its homologue, it facilitates lysis of target cells by creating holes in cell membranes.[259] FHL2-associated mutations may lead to a complete lack of protein or a defect in protein maturation/transport, leading to varying degrees of perforin deficiency and lymphocyte-mediated cytotoxicity.[258,260]

Whereas FHL2 is attributed to primary defects in the effector function of cell-mediated toxicity itself, FHL3, FHL4, and FHL5 are attributed to mutations in protein components of the trafficking machinery required for exocytosis of cytotoxic granules. Prior to exocytosis, vesicles must associate or "dock" with the membrane, a process facilitated by soluble NSF-attachment proteins (SNAP) on the vesicular compartment surface and SNAP receptors (SNAREs) on the target membrane (Fig. 64-7). Mutations in the gene that encodes the putative vesicular SNAP, syntaxin-11 (STX11), are responsible for FHL4.[261] A mammalian homologue of the *Caenorhabditis elegans* protein UNC13, known as UNC13D (also known as MUNC13-4), is mutated in patients with FHL3.[262,263] UNC13 family members are thought to participate in preparing vesicles docked at the cell surface for fusion with the membrane—a process called "priming."[264,265] The binding of STX11 with STXBP2 regulates granule docking and initiation of SNARE complex formation. Mutations in STXBP2, also known as MUN18-2, are associated with FHL5, which is also often associated with colitis and hypogammaglobulinemia.[266-268] Thus it would appear that STX11, STXBP2, and UNC13D are necessary to deliver *PRF1* extracellularly.[269] In toto, then, the deficiency of NK cell function in patients with FHL can be ascribed to a defect in the primary cytotoxicity effector pathway, leading to poor clearance of target cells and a

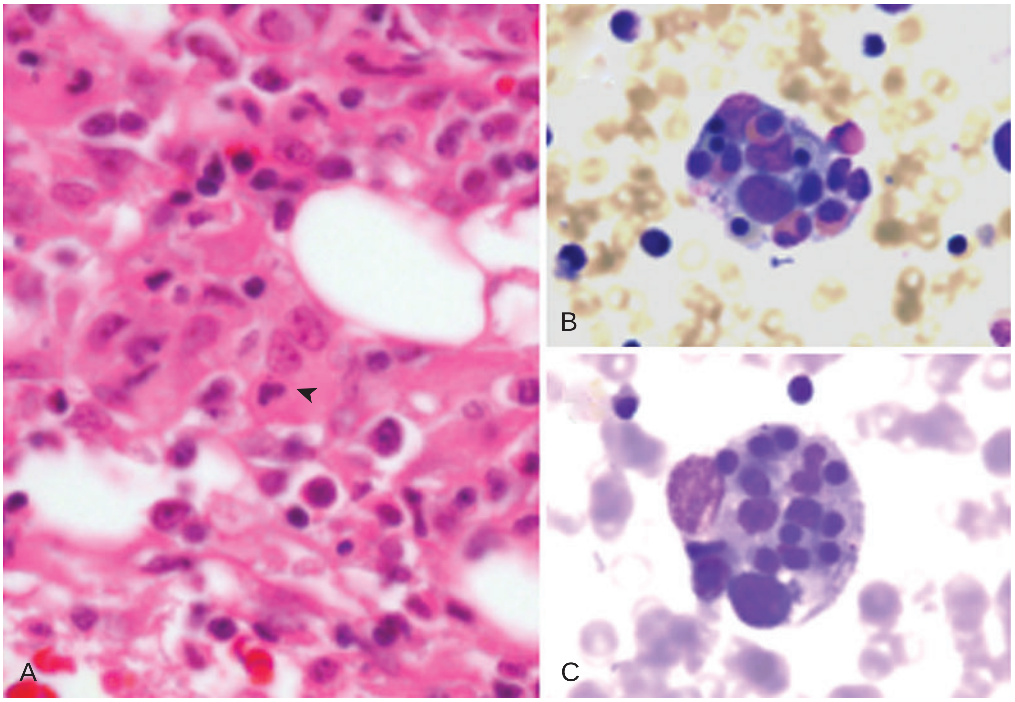

Figure 64-7 Histopathologic findings of hemophagocytic lymphohistiocytosis. **A,** A hematoxylin and eosin–stained bone marrow biopsy section (400× magnification) showing marrow infiltration by benign-appearing macrophages. A macrophage containing a phagocytosed neutrophil is indicated by the *arrowhead*. **B** and **C** show individual macrophages from a Wright-Giemsa–stained bone marrow aspirate smear (1000× magnification) that contain phagocytosed marrow elements, including mature eosinophils and erythroid precursors in **B** and numerous erythroid precursors and a band neutrophil in **C**.

continued state of immune activation, which is characteristic of the hemophagocytic syndromes.

Whereas the absolute frequency of disease-causing mutations in each of these genes varies greatly from publication to publication and population to population, it is evident that up to 80% of *molecularly defined* cases of FHL are attributable to mutations in *PRF1*, *UNC13D*, or *STXBP2*. *STX11* mutations are rare.[263,270-272] Despite the recent progress in the understanding of the genetic basis of FHL, a subset of presumptive FHL cases evade genetic characterization.

HLH Associated with Other Genetic Syndromes

HLH may occur in association with other inherited anomalies, including Chédiak-Higashi syndrome,[273] Griscelli syndrome type 2 (GS2),[274,275] lysinuric protein intolerance (LPI),[276] and X-linked lymphoproliferative syndrome (XLP1 and XLP2).[277,278] In these patients, hemophagocytosis is a variable feature, and it is not the sole manifestation of the disease. These disorders are diverse, with each disorder resulting from defects in distinct genes (Table 64-1).

Not coincidentally, the proteins encoded by the genes involved in several of these disorders each play a role in the process of cellular cytotoxicity. The GS2 protein labeled RAB27A, which is a small guanosine triphosphatase of the RAS-associated family, directly associates with the FHL3 protein labeled UNC13 and is similarly thought to regulate exocytosis.[279] Chédiak-Higashi syndrome, like GS2, gives rise to pigmentation defects and is also due to mutations in a protein, LYST, that is involved in vesicular trafficking. Patients with XLP1 as a result of mutations in the Src homology 2 domain–containing gene 1A (*SH2D1A*), which functions as a lymphocyte signaling adapter, have a multifactorial humoral and cellular immune deficiency most saliently characterized by susceptibility to EBV infection, lymphoproliferative disorders, and dysgammaglobulinemia (see Chapter 24).[280] Defects in NK cell and T-cell development and function, including cytotoxicity, appear to predispose patients with XLP1 to HLH, particularly in the setting of primary EBV infection. How abnormalities in dibasic amino acid transport[281] should result in HLH is completely obscure; however, several persons with LPI have presented with HLH.[276]

Secondary Hemophagocytic Lymphohistiocytosis

Infection-Associated HLH

Virus-associated hemophagocytic syndrome was first described in a report of 19 adult patients, 14 of whom were immunocompromised.[217] Subsequently, it was shown that this disorder also may develop in immunocompetent persons. Although viruses, especially EBV and other members of the herpes virus group, are the most commonly identified infectious triggers, a host of other infectious agents have been implicated, including bacteria,[218] fungi, and protozoa (e.g., leishmania).[282] In a review of the 219 cases of infection-associated hemophagocytic syndrome reported in the medical literature between 1979 and 1995, 55% were attributed to EBV.[39] The clinical features of infection-associated HLH are identical to FHL, although the median age of onset is higher; about 50% of cases occurred in children younger than 3 years and 18% of cases occurred in children younger than 1 year. An interesting but as yet unexplained fact is that about half of reported cases are in people of Asian ancestry.

Malignancy-Associated HLH

HLH occurs rarely in association with a malignant neoplasm in children, and in these rare instances it is most frequently associated with T-cell malignancies. The association presents in two uncommon but somewhat distinct forms: during treatment for a known cancer in clinical remission (e.g., acute lymphoblastic leukemia)[283] or as a manifestation of an aggressive uncontrolled cancer that may be masked (e.g., T-cell or NK-cell leukemia/lymphoma). In the first case, the clinical features of HLH arise unexpectedly in a patient undergoing cancer chemotherapy, presumably as a result of iatrogenic immune dysregulation. An infectious trigger may or may not be identified.[284] In the latter case, which occurs more commonly in adults, the hemophagocytic syndrome is a feature of the hematologic malignancy itself.[285,286] It is proposed that the malignant clone potentiates a state of hypercytokinemia that results in the clinical signs and symptoms of HLH. Interestingly, some of these cancers are associated with EBV infection. The majority of the reported cases are in persons of Asian descent.

Macrophage Activation Syndrome

Macrophage activation syndrome (MAS) is a life-threatening complication of systemic inflammatory conditions that is characterized by all of the clinical symptoms and laboratory findings of HLH, leading to its classification as a form of sHLH. The syndrome was first described in 1985 in a report of seven children with systemic onset juvenile idiopathic arthritis (S-JIA).[287] Rheumatologic conditions other than JIA, such as systemic lupus erythematosus, may also be associated with the syndrome in both children and adults. Typically the syndrome develops years after the diagnosis, but it may occur early on or even concomitantly with the diagnosis of the rheumatologic disease.[288] With the onset of MAS, the chronically ill child may experience unremitting fever, a decrease in blood cell counts, and organomegaly. Interestingly, the erythrocyte sedimentation rate may decrease concomitant with the development of MAS. Flare-ups of the underlying disease, infection, and medication adverse effects not only mimic MAS but might also trigger the events.[289,290] Ravelli[290] proposed MAS diagnostic guidelines after examining clinical and laboratory characteristics of patients with active S-JIA compared with S-JIA–associated MAS. According to the guidelines, the diagnosis of MAS rests on the presence of two or more laboratory criteria (platelets $\leq 262 \times 10^9$/dL; aspartate aminotransferase >59 U/L; white blood cell count $\leq 4.0 \times 10^9$/dL; fibrinogen ≤ 2.5 g/L) or any two or more laboratory or clinical criteria (e.g., CNS dysfunction, hemorrhages, or hepatomegaly).[291] Distinguishing MAS from FHL and forms of sHLH can also be a challenge.[292]

It has been suggested that inherited defect(s) in one or more of the genes associated with FHL might confer predisposition to the development of MAS in the setting of rheumatologic disease or, moreover, to the development of the rheumatologic condition itself.[293] A review of 133 children with S-JIA and 384 matched unrelated control subjects failed to demonstrate an increased incidence of detectable abnormalities in the genes encoding perforin, MUNC13D, Granzyme B, or RAB27A.[294]

Recently, a form of sHLH has been observed in some children and adults treated with T-cell activating therapies using blinatumomab[295] and chimeric antigen receptor bearing T cells[296] for refractory leukemia. The cytokine release syndrome that occurs in this context may be successfully managed with corticosteroid and the IL-6 receptor antagonist tocilizumab. Remarkably, the development of cytokine release syndrome is associated with antileukemia efficacy in treated patients.

Management

The development of specific and effective therapy for HLH is hampered by the fact that affected patients demonstrate common clinical features despite variable underlying pathophysiologic conditions. Additionally, there may be little time to wait for diagnostic clarity in affected patients. Whether the patient has FHL or sHLH, the first objective of therapy is to cool down an overheated immune response. At the same time or later, the underlying basis of the patient's disease process must be determined and addressed.

Without therapy, FHL is rapidly and invariably fatal, usually within a month or two of presentation. A comprehensive literature review performed prior to the discovery of effective chemotherapy showed that only 12% of children survived 6 months and just 3 of 101 children survived long term.[297] sHLH is also a life-threatening condition, although the outcome is much more variable. It is estimated that without therapy, the mortality rate for EBV-associated HLH is approximately 50%.[39]

In 1980, Ambruso and colleagues[298] first reported the successful treatment of two infants who had presumed FHL with etoposide (VP-16). This report was an enormous step forward because no effective therapy for the disease had previously existed.[299] However, disease control proved to be transient in these and subsequent patients, with the CNS being a major site of treatment failure. To address the problem of CNS disease, cranial irradiation or intrathecal methotrexate was added to the combination of VP-16 and corticosteroid.[300] Systemic and CNS relapses remained a significant problem and few, if any, patients survived long term. In most of the reported cases, patients who received maintenance therapy with etoposide eventually died of refractory disease within 1 to 3 years.[300,301] Teniposide, also an epipodophyllotoxin, has been used in some patients who have HLH with roughly equivalent results.[302]

In 1986, the first successful matched sibling donor bone marrow transplant in a boy with FHL was described.[303] HCT was quickly recognized as the sole potentially curative modality for this group of patients who previously had no real possibility of cure. However, allogeneic transplantation, which is always a high-risk procedure, is particularly toxic in children with HLH. Control of the clinical signs of HLH prior to transplantation significantly improves the likelihood of a successful outcome.[304,305] Additionally, absence of CNS involvement and infection are favorable indicators.[237] These factors drive the preference for early transplantation, which should be performed as soon as possible after the achievement of disease control and prior to the onset of CNS manifestations or the acquisition of an opportunistic infection.

Initial Therapy

To standardize, improve, and study the treatment of this rare disease, the Histiocyte Society sponsored an international clinical trial that was named HLH-94.[306] This study and its successor, HLH-2004, defined a set of clear diagnostic criteria and laid out a nonrandomized treatment strategy that combined chemotherapy (etoposide, glucocorticoids, and intrathecal methotrexate in select cases), immunotherapy (cyclosporine A), and HCT (when possible in familial, refractory, or relapsing cases). The HLH-94 study enrolled 249 eligible children between 1994 and 2003. Because it is impossible to differentiate FHL from sHLH at onset in many cases, confirmation of familial disease was not required, and therefore both familial and secondary cases were included. Overall, 86% percent of the children responded to 8 weeks of initial therapy, approximately 60% of whom achieved nonactive disease. Factors associated with early death included marked hyperferritinemia, hyperbilirubinemia, and CSF pleocytosis at diagnosis and persistent fever, thrombocytopenia, and hyperferritinemia after 2 weeks of treatment.[307] Half of the patients taking HLH-94 underwent transplantation, with a median time between onset of therapy and HCT of 6 months. Overall survival at 5 years among the 124 patients who underwent HCT was 66% versus 54% for the entire study population. No patients with verified FHL survived without HCT.[307]

The combination of antithymocyte globulin (ATG), corticosteroid, and cyclosporine A (CSA) is an alternative to HLH-94 chemoimmunotherapy, although experience with it is more limited. Among 38 children with confirmed FHL who received one or two courses of rabbit ATG, complete resolution was achieved in 73% and partial improvement was noted in 24%. This finding includes responses seen among 10 children who had received prior immunosuppressive treatment (including steroids, CSA, or chemotherapy). All of the patients received maintenance therapy with CSA. Sixteen of 19 patients who proceeded to receive an allogeneic transplant after being treated with ATG as first-line therapy are long-term survivors. All patients who did not undergo transplantation died. The therapy was relatively well tolerated, although infusional and infectious complications were not trivial.[308,309]

Newer agents with inhibitory effects on T cells and cytokine production are being developed. These approaches are attractive because they may directly interfere with the hyperinflammation that is responsible for the clinical features of HLH without the adverse effects of cytotoxic chemotherapy. Alemtuzumab is a therapeutic monoclonal antibody that is directed against CD52, an antigen expressed on lymphocytes, NK cells, monocytes, and macrophages. Alemtuzumab seems to be effective as a bridge to transplant in patients with refractory HLH,[310] and it has been incorporated in reduced-intensity conditioning regimens in patients undergoing HCT for HLH.[310]

As stated previously, the CNS is not infrequently involved in children with HLH at diagnosis, and it is a major site of treatment failure in patients with advanced FHL. Prompt and aggressive initiation of systemic chemoimmunotherapy, followed by allogeneic stem cell transplant in familial, refractory, and relapsing cases, is the best strategy for minimizing the potential for CNS damage.[248] The role of CNS-directed therapy is not well established. Intrathecal methotrexate and cranial irradiation have been used in the context of systemic therapy. In the HLH-94 study, intrathecal methotrexate was reserved for patients in whom neurologic symptoms progressed or CSF abnormalities did not resolve after 2 weeks of systemic treatment. Interestingly, the same fraction of children (10 of 15) experienced normalization of neurologic symptoms by 2 months, whether or not they received intrathecal therapy. Intrathecal methotrexate does not appear to prevent the development of CNS manifestations in patients who do not undergo transplantation. Furthermore, intensive intrathecal methotrexate is not sufficient to reverse CNS manifestations in children with advanced FHL.[248] Cranial irradiation is now rarely used because of the lack of established efficacy and the potential long-term toxicities in these very young patients.

Management of Secondary HLH

HLH that is associated with EBV infection is the most common and best-studied type of infection-associated hemophagocytic syndrome, and it is the prototype of sHLH. Compared with children with infectious mononucleosis, children with EBV-HLH have higher EBV genome copy numbers as measured by quantitative polymerase chain reaction. The EBV copy number quickly decreases with the initiation of effective therapy and can be used as a marker of disease activity in these patients.[311] The role of antiviral agents (e.g., acyclovir) is not well established but is probably of limited benefit during the phase of active viral replication. Importantly, the need for immunosuppressive therapy is well established in these patients. The efficacy of HLH-94-based immunochemotherapy has been clearly demonstrated, yielding a survival rate of up to 90% in patients who are treated promptly.[312] Because of the potential short-term (myelosuppression) and long-term (secondary myelodysplastic syndrome/acute myelogenous leukemia) toxicities linked to etoposide,[313] its role has been specifically evaluated. Mortality was 14 times higher for patients with EBV-HLH who did not receive etoposide within the first 4 weeks after diagnosis.[314] The risk associated with a relatively short course of etoposide appears to be justified when weighed against the high risks of morbidity and mortality in these patients and the knowledge that delayed treatment yields inferior outcomes. In a series of 78 patients with EBV-HLH, most of whom were treated according to the HLH-94 study protocol, 75% remain disease free, with a median follow-up of 43 months. Reactivations occurred in approximately 20% of cases, and many of these patients were eventually cured by HCT.[315]

A complementary therapeutic strategy for EBV-HLH is the use of B-cell directed therapy, which reduces the burden of EBV-infected B cells. Two young men known to have XLP and who were diagnosed with acute infectious mononucleosis were treated with rituximab (anti-CD20 monoclonal antibody) in combination with corticosteroids and responded favorably.[316] Recently, a retrospective review of 42 patients with EBV-HLH, some of whom proved to have FHL, demonstrated that rituximab in combination with conventional HLH-directed therapy is well tolerated and leads to improvement in HLH disease manifestations and a reduction in the EBV viral load.[317]

When sHLH occurs in association with visceral leishmaniasis, a very uncommon infection in the United States, treatment of the underlying infection with amphotericin B is usually lifesaving.[282]

Treatment of HLH and MAS that is associated with malignancy must be individualized. When an active malignancy is responsible for the hemophagocytic syndrome, administration of tumor-directed cancer chemotherapy is the best treatment choice. The clinical features of HLH can be expected to resolve if the triggering cancer is controlled. For the very rare patients in whom HLH develops while they are receiving immunosuppressive therapy for a cancer that is in remission, the best strategy is not known.[318] Discontinuation of immunosuppressive therapy is beneficial in some cases but is not always possible. Treatment with corticosteroids and etoposide may be indicated. When standard therapy for HLH fails, HCT should be considered.

MAS and rheumatologic disease-associated HLH fall into a clinical spectrum within which there are no generally accepted distinctions or definitions. MAS is a term that arose in the rheumatology literature and has become more or less synonymous with reactive HLH. It is likely that many patients in this disease spectrum do not come to the attention of pediatric hematologists/oncologists because their cases are managed by pediatric or adult rheumatologists. Some differences in approach exist between the two groups of specialists. High-dose, parenteral, pulsed corticosteroids are usually used in the initial management of MAS. CSA may be effective when corticosteroids lack efficacy.[319] More recently, inhibitors of TNF—etanercept[320] and infliximab[321]—have been used successfully in patients with MAS that is refractory to steroids and cyclosporine.

In patients in whom HLH resolves completely and for whom a cause of the syndrome is not determined (i.e., they lack a positive family history or an identified genetic defect), HCT is not indicated. Very close monitoring in the period after cessation of therapy is warranted. Patients who remain well are presumed to have had sHLH. In the subset of patients who manifest signs of disease reactivation, chemoimmunotherapy should be promptly reinstituted to control the disease prior to HCT.

Supportive Care

Some of the improvement in prognosis observed in the past decades in persons with HLH is attributable to advances in supportive care. New onset and uncontrolled cases of HLH are typically characterized by the presence of multiple organ system dysfunction, including immunologic compromise, pancytopenia, hemorrhagic tendency, and hepatic and neurologic dysfunction. Hemodynamic instability, respiratory insufficiency, renal dysfunction, and electrolyte imbalance may be present. Immunosuppressive and myelosuppressive chemotherapy in these critically ill patients magnifies their risk for serious infection. A significant fraction of children with HLH succumb to opportunistic infection. Empiric antibiotics for febrile neutropenia and pneumocystis, along with fungal prophylaxis and intravenous immunoglobulin repletion, are suggested. These interventions—along with other supportive care measures, including aggressive blood product support—contribute substantially to the likelihood and quality of survival.

Hematopoietic Cell Transplantation

Multiple studies have demonstrated the necessity for an allogeneic transplant in the management of FHL. In the International Registry report of 122 children with HLH, HCT was performed in 29 children, for whom the 5-year survival after HCT was 66%. Most of the donors were fully matched or mismatched family donors, and only three children received transplants from unrelated donors. Among patients who did not undergo transplantation, the 5-year survival rate was only 10%, with just three children surviving long term.[237] Because only a minority of the patients received HCT, the 5-year event-free survival for the entire cohort of 122 patients was just 21%.

The fact that only approximately 20% of children in need of an allogeneic stem cell transplant have an available matched family donor accounts in part for the poor overall survival among patients in the International Registry. Aside from human leukocyte antigen compatibility, another limitation to the applicability of matched sibling donor transplantation in a genetic disorder such as HLH is the possibility that the sibling donor is at risk for developing the disease. These factors, combined with the knowledge that FHL is invariably fatal without transplantation, has led to the increased use of unrelated and alternative donors.[305,322,323] The 3-year overall survival rate was 44% among 16 children with HLH who underwent transplantation with marrow from unrelated donors. Among the 65 children on the HLH-94 protocol who underwent transplantation, approximately half of whom received marrow from an unrelated donor, the 3-year probability of survival was 62%. The impact of expanded access to HCT by increased use of alternative donors (among other factors) was borne out in the relatively high overall survival rate of 55% at 3 years in the HLH-94 study. Disease remission at the time of transplantation is associated with a superior outcome after HCT.[322] However, HCT should not be viewed as futile in a child

TABLE 64-2 Comparison of Langerhans Cell Histiocytosis and Hemophagocytic Lymphohistiocytosis

	LANGERHANS CELL HISTIOCYTOSIS		**HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS**	
	Single System	**Multisystem**	**Primary**	**Secondary**
Pathologic cell	Dendritic cell		Macrophage	
Histologic features	Clonal Langerhans cell proliferation (CD1a+, Langerin+) Mixed cellular infiltrate		Reactive macrophages (CD68+) hemophagocytosis	
Typical age at onset	Childhood	Infancy	Infancy	Childhood
Inheritance	Sporadic	Sporadic	Autosomal recessive	Sporadic
Clinical presentation	Bone pain/swelling Skin rash	Bone pain/swelling Skin rash, FTT, DI	Fever, hepatosplenomegaly, irritability, jaundice	
Laboratory/ radiographic features	Laboratory tests usually normal/lytic bone lesions	Cytopenia(s), liver dysfunction, bone lesion(s)	Cytopenias, ↑ferritin, ↓fibrinogen, ↑triglycerides, ↓NK function, ↑soluble CD25, abnormal CSF	
Treatment	Observation, vinblastine/steroids	Vinblastine/steroids	Etoposide/steroid/ CSA, HCT	Etoposide/steroid/CSA
Prognosis	Excellent	Variable Fatal in ≈25%	Fatal without HCT, Survival ≈50% with HCT	Variable Fatal in ≈20%

with active disease, even involving the CNS, because many children with active disease at the time of HCT have done well.[324] Despite high early mortality rates, late reactivation of disease is very uncommon in patients who have undergone allogeneic HCT for FHL.[324]

The most commonly used myeloablative conditioning regimen for HCT in patients with HLH is the combination of busulfan, cyclophosphamide, etoposide, and ATG. Transplant-related mortality is very high with this approach; roughly one third of recipients of transplants die after myeloablative conditioning within the first few months as a result of infection, hepatopathy, pneumonitis, or uncontrolled disease.[325] Reduced-intensity conditioning is increasingly recommended in this setting because it is associated with a significantly higher likelihood of survival.[168,326] Establishment of stable, long-term donor chimerism is an issue, and donor lymphocyte infusion is indicated in many cases. For this reason, reduced-intensity conditioning is not suitable for patients for whom the only acceptable donor source is umbilical cord blood.

CONCLUSIONS

HLH is an acute, rapidly progressive, potentially life-threatening syndrome. The clinical features are the consequence of hyperinflammation and immune dysregulation, but the underlying mechanisms are diverse. Prompt recognition and initiation of therapy is warranted, even when diagnostic certainty is elusive. Initial therapy with etoposide and a corticosteroid with or without the addition of CSA is the standard of care in the United States. Analysis for defects in the genes known to be associated with the condition should be undertaken, although not all familial cases will have a confirmatory genetic test. Assessment for triggers of secondary HLH should be pursued, but identification of an infectious trigger does not reliably differentiate FHL and sHLH. Children who have FHL based on a positive family history, the finding of a genetic abnormality, or a refractory or relapsing course should be referred for allogeneic hematopoietic stem cell transplant as soon as possible. Children not known to have FHL based on these criteria may be observed if they achieve disease resolution after 2 to 3 months of initial therapy. A comparison of some of the cardinal features of LCH and HLH is shown in Table 64-2.

Diagnosis and Staging
Treatment
Screening and Preventive Therapy for At-Risk Children
Follow-Up Observation
URINARY BLADDER CARCINOMA
OVARIAN TUMORS
Stromal Carcinomas
TUMORS OF THE CERVIX AND VAGINA
GESTATIONAL TROPHOBLASTIC TUMOR
MELANOMA
Epidemiology
Risk Factors
Clinical Molecular and Pathologic Features
Diagnosis and Staging
Treatment and Outcome

This chapter covers the rare tumors of childhood. No attempt has been made to consider the rarest of the rare tumors, and the focus is on the more common of the rare pediatric tumors that do not fall into other categories covered in this text. The chapter is generally organized from top to bottom, with cancers of the head and neck at the beginning and cancers of the gastrointestinal tract discussed later in the chapter. The tumors discussed afflict mostly adults, and some are actually common cancers in older patients. Many are carcinomas and are more familiar to the oncologist who treats adults. These cancers tend to increase in incidence as children reach adolescence.

Evaluation of Surveillance, Epidemiology, and End Results (SEER) data has shown that 9.2% of all childhood cancers are carcinoma, and 75% of these cases are diagnosed in children between the ages of 15 and 19 years.[1] Of the cases in the study, 36% were thyroid carcinomas and 31% were melanomas. The next most common single carcinoma in children younger than age 19 years was nasopharyngeal carcinoma, which comprised 4.5% of these cases. Thus this chapter emphasizes discussion of melanoma, thyroid carcinoma, and nasopharyngeal carcinoma and reviews other rare tumors of childhood.

OROPHARYNGEAL CANCER

Oropharyngeal cancer of squamous cell histology in children remains uncommon.[2] Most of the children who develop epithelial cancer of the nose, ears, and throat are diagnosed with nasopharyngeal carcinoma, which is considered separately in this chapter. The use of smokeless tobacco, cigarette smoking, and alcohol consumption are well established risk factors for the development of squamous cell carcinoma in adults, and the continued use of these substances in Western children warrants monitoring for the development of adult types of squamous cell carcinoma of the oropharynx in children. Although such habits ultimately lead to increased risk for a variety of cancers and early death from heart disease, it remains a theoretical concern that the use of smokeless tobacco by children, particularly by male adolescents, could increase the incidence of these tumors during adolescence and young adulthood.

Duration of smoking increases risk for tobacco-related morbidity and mortality, including several cancers, and significant public health efforts have been aimed at reducing adolescent initiation of tobacco use.[3] Educational interventions have been shown to decrease the prevalence of cigarette and smokeless tobacco use in Massachusetts youth,[4] but restrictions on tobacco sales have a mixed record, because even a complete ban on sales of smokeless tobacco in Finland did not lead to a decrease in its use by adolescents.[5] Conversely, restrictions on smoking in public places have been demonstrated to decrease overall tobacco consumption (e.g., by up to 8% in Italy).[6] Overall trends of cigarette smoking among adolescents have decreased steadily since the mid-1990s. Rates of smoking for white, non-Hispanic twelfth grade students are significantly higher in comparison to Hispanic and African-American students.[3,7,8] Although smokeless tobacco use also declined during the late 1990s and early 2000s, recent data from Monitoring the Future and the National Youth Tobacco Survey have demonstrated increased use in recent years, with concurrent decreased reporting of perceived risk. These changes in trends are synchronous with aggressive marketing campaigns by tobacco companies of novel delivery forms of smokeless tobacco such as “snus” and dissolvable tobacco.[7,9]

The increasing prevalence of human papillomavirus (HPV) infection in adolescents and young adults has raised new concerns about the development of HPV-associated oral squamous-cell carcinoma in younger patients. HPV has recently been detected in approximately 26% of head and neck squamous-cell carcinomas; HPV16 was highly prevalent among these tumors.[10] Trends in adults show an increasing incidence in oral squamous-cell carcinomas despite declining use of tobacco in the United States because of the increasing prevalence of oral HPV infection.[11,12] A recent study showed 1.7% of 14- to 17-year-old adolescents and 5.6% of 18- to 24-year-old adults had oral HPV; male sex, number of sexual partners, tobacco use, open-mouth kissing, and oral sex have been associated with infection.[13,14] HPV is most often transmitted in adolescence and young adulthood; a quadrivalent vaccine for HPV that includes strains likely to cause oral cancers is now available and is recommended for both boys and girls.[15,16]

Few existing studies report outcomes of pediatric squamous-cell carcinomas. A population-based study of 54 pediatric patients with oral-cavity squamous-cell carcinoma had a 5-year disease-specific survival rate of 75%.[17] It is unlikely that many pediatric oncologists will be confronted by adult-type squamous-cell carcinoma of the head and neck, but it is likely that pediatric oncologists will be confronted with tobacco use in young adult and adolescent survivors of pediatric cancer. A St. Jude Children’s Research Hospital study has found that 29% of surviving children treated on an acute myelogenous leukemia (AML) protocol were found to be cigarette smokers at follow-up examinations.[18] Although survivors of childhood cancer may not be seen often in the pediatric oncology clinic, tobacco use and prevention still merit mention during such visits.

Mucoepidermoid carcinoma of the salivary glands is still another type of head and neck carcinoma from which children suffer and is commonly associated with prior therapy for cancer, including radiation.[19] A study of childhood cancer survivors identified 23 cases of secondary head and neck malignancies; of the 14 secondary cancers that arose in the parotid gland, 10 were identified as mucoepidermoid carcinoma.[20] Most children are cured with surgery and sometimes surgery and radiation therapy. Any mass lesion or presenting complaint potentially related to a mass lesion in the salivary glands, particularly if found in a previous radiation field, should prompt a thorough evaluation with suspicion for this tumor.

NASOPHARYNGEAL CARCINOMA

Nasopharyngeal carcinoma is a cancer of the epithelial lining of the nasopharynx. It shows varying degrees of differentiation but is a type of squamous-cell carcinoma. Most cases have undifferentiated histology; the undifferentiated type is associated with Epstein-Barr virus (EBV) infection of the nasopharyngeal epithelium, and virus is found in the tumor cells.[21] It is the most common type of epithelial tumor of the head and neck in children, accounting for up to 50% of head and neck tumors in children. Incidence varies widely among populations and in relationship to exposure to EBV, environmental exposures such as preserved or salted fish, and geographic location. Rates in China are particularly high, and ethnic Chinese born in China who move to the West have a higher incidence of the disease than ethnic Chinese who are born in Western countries.[21] In the United States, this cancer is more common in the South and more prevalent in African-American children, who have incidence rates of the disease that approach those of the Chinese. These findings suggest interplay of genetic, viral, and environmental factors in the carcinogenesis of nasopharyngeal carcinoma.

Analysis of incidence and survival rates from SEER data has demonstrated improved survival for Asian-American patients compared to Caucasian and African-American patients. However, nasopharyngeal carcinoma-specific mortality is worse for adults than for children and adolescents, and survival rates in the adolescent and young-adult age ranges tend to be similar among races.[22-25]

Epidemiology

Nasopharyngeal carcinoma is more common in Asia and is strongly associated with Chinese ethnic origin within Asia, with some parts of China having incidence rates from 15 to 30 cases per 100,000 population.[21] There is also a higher incidence of the cancer in Turkey.[26,27] A bimodal age distribution has been suggested in nonendemic areas, with an early peak in adolescents age 15 to 19 years.[28] The actual cancer cells are infected by EBV, suggesting a possible role for immunosuppression in the pathogenesis of the tumor, or at least that immune augmentation could help prevent recurrence of nasopharyngeal carcinoma.[21] In Greenland and other regions with similar native populations, high rates of nasopharyngeal carcinoma have been found. Additionally, high rates for other cancers associated with EBV infection, such as various forms of uterine cancer, are more common in families with EBV and nasopharyngeal carcinoma.[29,30] Population-based screening based on EBV serology in endemic areas can help detect nasopharyngeal carcinoma early. However, this would be impractical in nonendemic areas.

Presentation

The typical presenting signs and symptoms of nasopharyngeal carcinoma include evidence of tumor mass in the nasopharynx such as epistaxis, nasal obstruction and discharge, Eustachian tube dysfunction, palsy of the fifth and sixth nerves relating to skull-based extension, and neck masses.[21] In children with epidemiologic factors making this disease more likely, clinicians must maintain a high index of suspicion for nasopharyngeal carcinoma and obtain imaging studies and consultation as necessary for these signs and symptoms. However, most children diagnosed with nasopharyngeal carcinoma in the United States are unlikely to have obvious epidemiologic associations for the cancer, and even in the United States EBV infection in childhood is common enough that screening based on evidence of EBV infection would be impractical.

Staging and Evaluation

Proper evaluation of patients suspected of having nasopharyngeal carcinoma includes computed tomography (CT) scan and/or magnetic resonance imaging (MRI) of the head and biopsy of appropriate tissue for diagnosis. A clinical examination is key to evaluate for any apparent lymph node spread. Although systemic evaluation, including laboratory testing, positron emission tomography (PET) scanning, whole-body anatomic scanning, and bone marrow biopsy can be considered, they have not been shown to improve staging accuracy in patients with nasopharyngeal carcinoma.[21]

All nasopharyngeal carcinoma cases are considered squamous-cell cancers, but the World Health Organization (WHO) classification of nasopharyngeal carcinoma defines type 1 histology as keratinizing squamous-cell carcinoma, a form of cancer more common in adults, versus the type 2 histology, which does not show keratinization on light microscopy but does show some differentiation. Type 3 histology is nonkeratinized and nondifferentiated and is associated with endemic nasopharyngeal carcinoma.[21] The majority of children with nasopharyngeal carcinoma have a presentation of undifferentiated or WHO type 2 or 3 histology.[23]

The American Joint Commission on Cancer (AJCC) tumor-nodes-metastasis (TNM) staging system (2010) is considered the most relevant for patients in the Western countries. The WHO staging system has fewer local (T) staging categories but seems to be adequate for patients in endemic areas.[21,31] The latest AJCC staging system is shown in Tables 65-1 and 65-2.

TABLE 65-1 Tumor-Nodes-Metastasis Definitions for Nasopharyngeal Carcinoma*

Primary Tumor (T)	Regional Lymph Nodes (N)	Distant Metastasis (M)
TX: Primary tumor cannot be assessed T0: No evidence of primary tumor Tis: Carcinoma in situ T1: Tumor confined to the nasopharynx, or tumor extends to oropharynx and/or nasal cavity without parapharyngeal extension† T2: Tumor with parapharyngeal extension† T3: Tumor involves bony structures of skull base and/or paranasal sinuses T4: Tumor with intracranial extension and/or involvement of cranial nerves, hypopharynx, orbit, or with extension to the infratemporal fossa/masticator space	NX: Regional lymph nodes cannot be assessed N0: No regional lymph node metastasis N1: Unilateral metastasis in cervical lymph node(s), ≤6 cm in greatest dimension; above the supraclavicular fossa and/or unilateral or bilateral; retropharyngeal nodes, ≤6cm in greatest dimension‡ N2: Bilateral metastasis in cervical lymph node(s), ≤6 cm in greatest dimension; above the supraclavicular fossa‡ N3: Metastasis in a lymph node(s)‡ >6 cm and/or to supraclavicular fossa N3a: >6 cm in dimension N3b: Extension to the supraclavicular fossa§	M0: No distant metastasis M1: Distant metastasis

*The distribution and prognostic impact of regional lymph-node spread from nasopharynx cancer, particularly of the undifferentiated type, are different from those of other head and neck mucosal cancers and justify the use of a different regional lymph-node classification scheme.

†Parapharyngeal extension denotes posterolateral infiltration of tumor.

‡Midline nodes are considered ipsilateral nodes.

§Supraclavicular zone or fossa is relevant to the staging of nasopharyngeal carcinoma and is the triangular region originally described by Ho. It is defined by three points: 1) the superior margin of the sternal end of the clavicle; 2) the superior margin of the lateral end of the clavicle; and 3) the point where the neck meets the shoulder. Note that this would include caudal portions of levels IV and VB. All cases with lymph nodes (whole or part) in the fossa are considered N3b.

*Results of radiation therapy for nasopharyngeal carcinoma (locoregional control and survival) are usually reported by T stage and N stage separately or by specific T and N subgroupings rather than by numerical stages I to IV. Outcome also depends on various biologic and technical factors related to treatment.

Treatment

Although nasopharyngeal carcinoma can be treated by radiation therapy only, it has been shown to be sensitive to chemotherapy in adults and children. Using chemotherapy may ultimately allow for curative radiotherapy at lower doses with less risk for late effects from head and neck radiotherapy.[21,24,26-27,32] A Pediatric Oncology Group (POG) study used four cycles of preirradiation chemotherapy with methotrexate with leucovorin, 5-fluorouracil (5-FU), and cisplatin to treat children with AJCC stage III or IV nasopharyngeal carcinoma. Children with stage I or II disease were treated with irradiation only. The 4-year event-free and overall survival rates were 77% ± 12% and 75% ± 12%, respectively.[24] Other agents used to treat nasopharyngeal carcinoma include bleomycin and doxorubicin.[27] More recently, the use of neoadjuvant chemotherapy with concomitant chemoradiation has demonstrated improved outcomes.[21,26-27] Xerostomia and dental problems are common adverse effects of treatment. Other long-term morbidities include sensorineural hearing loss, endocrinopathies, trismus, and recurrent infections.[33] Sensorineural hearing loss incidence has been noted to increase with the use of concomitant chemoradiotherapy.[34] Although both children and adults with nasopharyngeal carcinoma are at risk of developing secondary malignancies after treatment, the risk for children is 4.3 times the general population, compared with 1.4 for adults.[23] Current treatment strategies are investigating the use of intensity-modulated radiation therapy (IMRT) and amifostine to preserve salivary function[35,36] and to decrease acute and chronic sequelae of therapy.

THYROID CARCINOMA

This section summarizes the clinical-pathologic and therapeutic aspects of differentiated thyroid carcinoma in children and adolescents. Medullary thyroid carcinoma (MTC) and associated multiple endocrine neoplasia (MEN) syndromes are not discussed.

Epidemiology

The prevalence of palpable thyroid nodules in children is lower than that seen in adults (1.5% vs. 5%); despite this, thyroid nodules in children are five times more likely to be malignant than those in adults (25% vs. 5%).[37-39] Of the estimated 56,000 cases of thyroid cancer diagnosed in 2012, only 1.8% occur in patients under 20 years of age.[40] Furthermore, thyroid carcinoma accounts for 3% of all cancers in patients younger than 20 years, and 75% of these occur in patients between the ages of 15 and 19 years (Fig. 65-1).[41] Epidemiological studies suggest that the incidence of thyroid carcinoma has steadily increased over time and that it affects both low and high socioeconomic counties that were surveyed by the SEER registries.[42,43] In pediatrics, an increasing rate has been documented in the SEER registry for the years 1973 through 2007, with the rates being higher in whites, those aged between 15 and 19 years, girls, and in registries with predominantly white or Hispanic populations.[44]

Radioactive exposure to the neck is a well-established risk factor for the development of thyroid carcinoma.[45] Survivors of childhood cancer have up to a 14-fold excess risk of developing thyroid cancer if their thyroid gland received 20 to 25 Gy, and this malignancy accounts for 10% of all subsequent neoplasm in the survivor population.[46,47] A risk-prediction model for subsequent primary thyroid carcinoma in survivors of childhood cancer has been developed.[48] This model incorporates several variables including radiation and therapy information, age, sex, and a history of a thyroid nodule; the software to compute risk projections can be downloaded at http://dceg.cancer.gov/tools/riskassessment.[48]

Exposure to radioactive iodine and cesium isotopes after the Chernobyl accident resulted in a markedly increased rate of thyroid cancer in children; the estimated relative excess risk was estimated to be 5.6 per Gy of exposure in subjects with estimated doses of less than 1 Gy.[49-51] Other risk factors associated with the development of pediatric thyroid cancer include various genetic syndromes such as familial adenomatous polyposis (FAP), Cowden disease, Carney syndrome, and immune thyroid disorders such as Hashimoto thyroiditis.[37,52-54]

Pathology and Molecular Pathology

More than 90% of pediatric thyroid carcinomas have well-differentiated histology; papillary histology accounts for over 70% of cases, and follicular histology represents about 20% of cases. Medullary thyroid cancer is seen in fewer than 10% of pediatric cases of thyroid cancer and can be found in association with MEN syndrome types

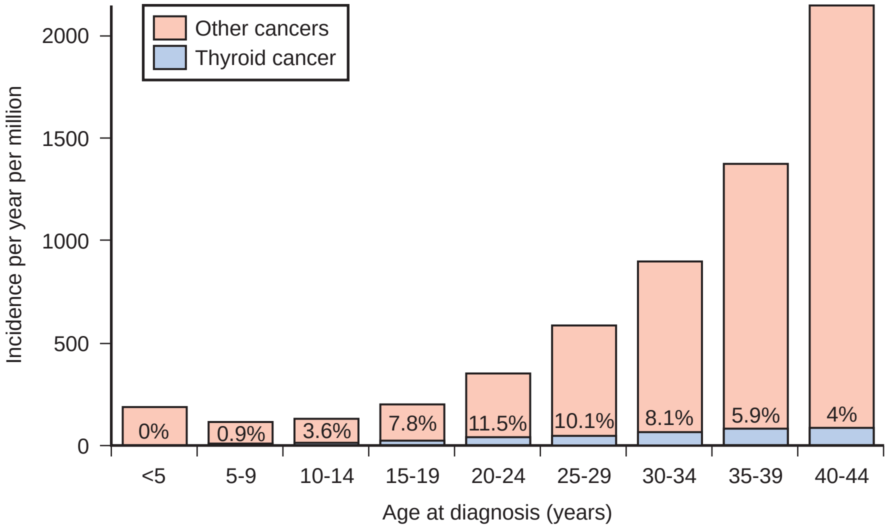

Figure 65-1 Incidence of thyroid carcinoma relative to all cancers, SEER 1975-2000. *(Data from Bleyer A, O'Leary M, Barr R, Ries LAG, editors:* Cancer epidemiology in older adolescents and young adults 15 to 29 years of age, including SEER incidence and survival: 1975-2000 [NIH Publication No. 06-5767]. *Bethesda, Md., 2006, National Cancer Institute.)*

2A and 2B.[55] The distribution of histologies varies slightly in cases with known radiation carcinogenesis; in a study of 740 children with thyroid cancer, of whom 92% were exposed to radiation at Chernobyl, 90% of cases were papillary, about 5% were follicular, and 0.4% were medullary.[56]

RET-PTC rearrangements have been documented in 50% to 60% of pediatric cases of papillary thyroid carcinoma and in up to 70% of radiation-induced pediatric papillary thyroid carcinoma.[54,57] *NTRK1* rearrangements and *AKAP9-BRAF* fusions have also been described in a small number of radiation-induced papillary tumors.[58-60] Unlike in adults, *BRAF* mutations are rarely seen in pediatric papillary tumors.[61-62] Follicular tumors are characterized by *RAS* mutations and peroxisome proliferator–activated receptor γ (PPARγ) rearrangements, whereas MEN-associated medullary thyroid carcinomas are characterized by germline-activating mutations of *RET*.[54,63]

Clinical Presentation and Staging

Most patients with thyroid carcinoma are older than 10 years and initially have an asymptomatic palpable thyroid nodule.[64] Younger age (<15 years), large fixed nodules, palpable adenopathy, history of radiation exposure, and diseases associated with an increased incidence of thyroid carcinoma such as FAP, Carney complex, Cowden syndrome, MEN types 2A or 2B, pheochromocytoma, and hyperparathyroidism should raise the suspicion for the presence of malignancy.

Children and adolescents with thyroid carcinoma are more likely to have nodal regional involvement, extrathyroid disease, and pulmonary metastases and are less likely to die from their disease than adults.[64] Ultrasound is a useful diagnostic technique, and most investigators prefer this method for evaluating thyroid nodules (Fig. 65-2).[37,64] Initial evaluation of a thyroid nodule should include measurements of serum thyroid-stimulating hormone (TSH), antithyroid peroxidase, antithyroid globulin antibodies, and a neck ultrasound that evaluates the contralateral thyroid lobe and cervical nodes.[39] Screening for MTC using plasma calcitonin may not be cost-effective in children given its low prevalence in the pediatric population.[37,39,65] If the TSH level is low, raising the possibility of a hyperfunctional nodule, a thyroid technetium or iodine scan should be performed. Because of the higher likelihood of malignancy in children, it is recommended that all hyperfunctioning nodules be surgically removed in children, with further evaluation and treatment should the pathology be consistent with malignant disease.[65,66] Fine-needle aspiration biopsy is the most cost-effective and expeditious preoperative procedure to help distinguish benign from malignant thyroid nodules; a meta-analysis of 12 pediatric studies found that this procedure has a sensitivity of 94% and a specificity of 81% (see Fig. 65-2).[37,67] Preoperative staging should include a chest x-ray and a comprehensive neck ultrasound to evaluate the whole thyroid and lymph nodes.[64]

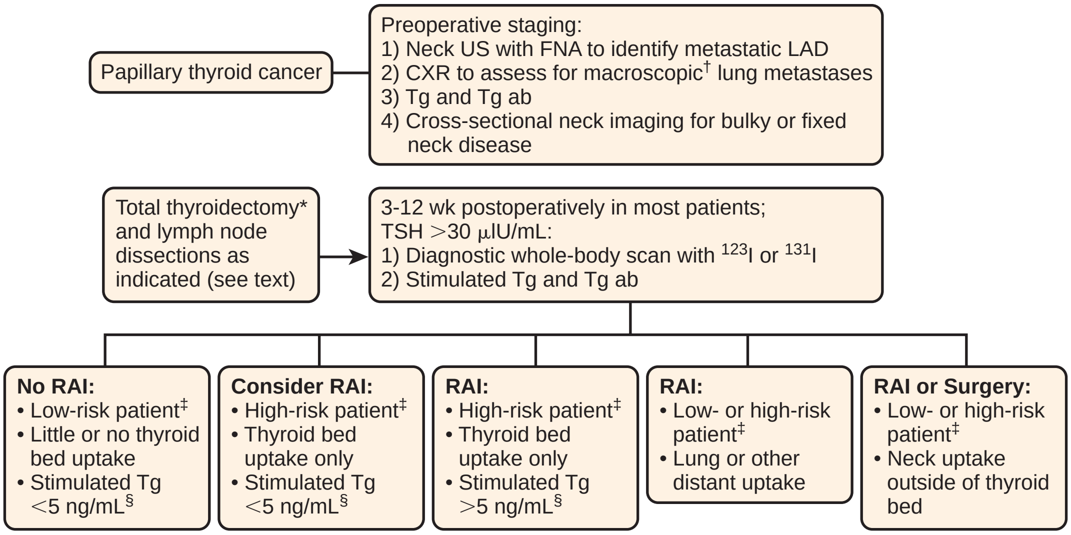
Prognostic Factors

Factors associated with an increased risk of progression include capsular invasion, soft-tissue invasion, positive margins of resection, age younger than 10 to 15 years, male sex, nonpapillary histology, distant metastases, and residual disease after surgery.[68,69,70] Survival for children with differentiated thyroid carcinoma approaches 100% (Fig. 65-3).

Treatment and Outcome

Surgery

Surgery is the mainstay of therapy for pediatric and adolescent thyroid carcinoma, and this procedure should be performed by a highly experienced thyroid surgeon.[64] Total thyroidectomy is the initial treatment of choice. especially in younger patients (<10 years) or those with a history of radiation exposure or a family history of



Papillary thyroid cancer
Preoperative staging:
1) Neck US with FNA to identify metastatic LAD
2) CXR to assess for macroscopic† lung metastases
3) Tg and Tg ab
4) Cross-sectional neck imaging for bulky or fixed neck disease
Total thyroidectomy* and lymph node dissections as indicated (see text)
3-12 wk postoperatively in most patients; TSH >30 μIU/mL:
1) Diagnostic whole-body scan with 123I or 131I
2) Stimulated Tg and Tg ab
No RAI:

High risk: any of the previous features present. §Assumes negative Tg ab. ¶RAI if no macroscopic disease on US; surgery if macroscopic disease on US. *(From Waguespack SG: Initial management and follow-up of differentiated thyroid cancer in children.* J Natl Compr Canc Netw *8:1289–1300, 2010.)*

thyroid cancer.[64] Many surgeons also advocate the upfront use of this procedure because pediatric thyroid carcinoma is associated with a high incidence of multifocal and metastatic disease, and follow-up screening with serum thyroglobulin is most useful after total thyroidectomy.[64,66] Lobectomy and isthmectomy can be considered in patients who have a low risk for recurrence such as adolescents with localized small (<1 cm) lesions.[64,71-73]

Lymph Node Dissection

Upfront nodal dissection has been shown to decrease the risk of surgical reintervention and nodal recurrence in children with thyroid carcinoma.[56,74] Current recommendations favor the use of central compartment neck dissection, reserving less extensive surgeries for patients with small tumors and no evidence of nodal involvement by ultrasound (see Fig 65-2).[64]

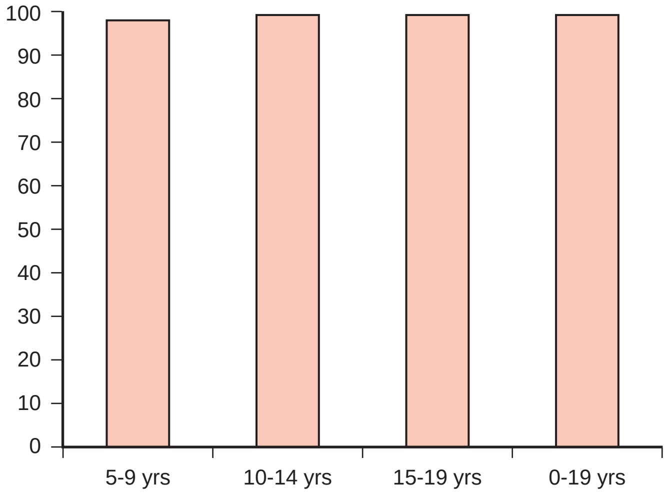

Figure 65-3 Five-year relative survival rates for thyroid carcinoma by age group, SEER 2002-2008.

Use of Radioactive Iodine

In adults, the use of radioactive iodine treatment to ablate residual thyroid or iodine-avid metastatic disease decreases the risk of distant metastases.[75] The goals for the use of this therapy in children includes ablation locoregional recurrence, elimination of residual sources of thyroglobulin production, and high remnant uptake that can obscure the presence of metastases and accurate detection of pulmonary metastatic disease.[76] The use of this therapy in children has been associated with a reduced recurrence risk in the thyroid and nodes independent of the surgical approach.[76] However, a recent study by Hay failed to show a significant difference in local and distant recurrence when this modality was used, and 73% of patients who died from a subsequent malignant neoplasm had received therapeutic irradiation postoperatively.[77] Radioactive iodine treatment should be reserved for children at high risk for disease recurrence, and a suggested measured approach for the postoperative use of this agent is shown in Figure 65-2.[64] When radioactive treatment is prescribed, TSH should be greater than 30 μIU/mL.[64] The dosing of this agent is not well established in children, and various centers follow the American Thyroid Association (ATA) guidelines for adults (*http://thyroidguidelines.net/revised/differentiated*). A posttherapy thyroid scan is usually obtained about 1 week after treatment, and this may identify additional sites of disease that were not apparent initially. Because of the risk of regrowth after TSH exposure, thyroid hormone suppression to achieve serum TSH levels between 0.1 and 0.5

μIU/mL is recommended in all pediatric patients with differentiated thyroid cancer.[64]

Targeted Therapies

A variety of "targeted" therapies have been developed for iodine-refractory differentiated thyroid carcinoma, and many of these agents have been approved for adult use.[78] Most of these therapies target RET and the vascular endothelial growth factor (VEGF) receptors but some also target platelet-derived growth factor β receptors (PDGFRβs), FGFR, MET, and endothelial growth factor (EGF) receptors.[78] Some of these agents include sorafenib, axitinib, motesanib, sunitinib, pazopanib, cabozantinib, and vandetanib.[78] In children sorafenib has been successfully used in a patient with refractory papillary thyroid carcinoma, and in a phase I/II study, vandetanib produced two partial responses in children with MEN2b-associated medullary thyroid carcinoma.[79,80]

Follow-Up Observation

Lifelong surveillance is recommended for children with thyroid carcinoma. A recent article recommends determination of suppressed thyroglobulin levels and antibodies every 3 to 6 months and a neck ultrasound every 6 to 12 months for the first 2 years of follow-up care.[64] If a patient was treated with radioactive iodine, a stimulated thyroglobulin test and whole body scan is recommended 1 year after initial treatment. About 25% of patients develop antibodies, and these interfere with the thyroglobulin assays. Declining antibody titers usually correlate with lower disease burden.[64]

BREAST TUMORS

Breast masses are rare in young children. During puberty, benign fibroadenomas are the most common cause of a palpable breast lump (Table 65-3).[81] The estrogen stimulation during adolescence may cause exaggerated growth of the stroma and epithelium in a localized breast lobule that characterizes a fibroadenoma. They have been found in as many as 20% of women between the ages of 15 and 25 years on autopsy studies.[82] Fibroadenoma occurring in adolescence does not appear to be associated with concurrent or future breast carcinoma. Any dominant discrete breast mass in an adolescent should be reexamined at midcycle after one or two menstrual cycles. Persistent masses should be imaged by ultrasound (not mammography) and referred to a surgeon. Typically, malignant breast masses in children have similar imaging characteristics to malignant breast masses in adults, which can help guide the decision to perform more invasive evaluation.[83] Lesions typical for fibroadenoma are sometimes observed clinically; fine-needle aspiration or core biopsy can also be performed to confirm the diagnosis.[84] Most fibroadenomas in adolescents self-resolve or shrink.[85] Most boys with breast masses have gynecomastia that requires only reassurance and noninvasive supportive care. This is borne out by review of pathology specimens from teenage male patients who underwent resection of breast masses; nearly all such evaluations were negative.[86]

Phyllodes tumors are stromal tumors that present as rapidly growing but clinically benign masses. Although the median age of presentation is 45 years, they can occur in adolescence.[87] Benign phyllodes tumors of the breast are pathologically similar to a large fibroadenoma with more stromal cellularity. They are treated by resection with at least 1 cm margins.[88] Malignant phyllodes tumors are sarcomas with nuclear pleomorphism and mitotic activity; treatment requires a multimodality sarcoma approach. Five-year disease-free survival rates have been reported to be 96%, 74%, and 66% for benign, borderline, and malignant phyllodes tumors, respectively, in adults[89]; it is thought that adolescents have a more favorable outcome.[90]

Breast masses can also represent primary or metastatic sites of pediatric cancers such as rhabdomyosarcoma,[91] non-Hodgkin lymphoma, Hodgkin lymphoma, or neuroblastoma.[92]

Breast carcinoma in a patient under the age of 20 years is rare; five cases were seen at M.D. Anderson Cancer Center over 10 years, compared with 180 cases in patients between ages 20 and 30 years and 1347 in patients between ages 31 and 50 years.[93] The most common pathology is a juvenile secretory carcinoma that secretes mucin and mucopolysaccharide-containing material. It is treated by excision and lymph node biopsy. No studies have evaluated outcomes in patients younger that the age of 20 years with breast carcinoma, but multiple studies have shown that age younger than 30 or 35 years is an independent predictor of poor response.[93] The two younger age groups at particular risk of breast cancer are women who have received radiation to the breast, usually for lymphoma, and women who have a familial predisposition. These women should be taught breast self-examination and awareness at a young age.

PULMONARY TUMORS

Primary tumors of the lung are extremely rare in childhood, and metastatic pulmonary lesions far exceed the number of primary tumors.[94] Table 65-4 lists the most common pulmonary tumors in children.

TABLE 65-4 Pulmonary Tumors in Children

Malignant	Benign
Bronchial adenomas (40% to 60%)	Hamartomas
Carcinoid	Hemangiomas
Mucoepidermoid carcinoma	Lymphangioma
Adenoid cystic carcinoma	Leiomyomas
Pleuropulmonary blastoma (15%)	Myofibroblastic tumors
Bronchogenic carcinoma (10% to 15%)	Inflammatory myofibroblastic tumor
Adenocarcinoma	Myofibromatosis
Small-cell carcinoma	Congenital peribronchial myofibroblastic tumor
Bronchoalveolar carcinoma	Neurogenic tumors
Squamous-cell carcinoma	Mature teratoma
Undifferentiated carcinoma	
Fetal-lung adenocarcinoma	
Pulmonary mesothelioma	
Sarcomas (20% to 25%)	
Rhabdomyosarcoma	
Synovial sarcoma	
Hemangiopericytoma (solitary fibrous tumor)	
Leiomyosarcoma	
Angiosarcoma	
Bronchopulmonary fibrosarcoma	

Bronchial Adenomas

A large percentage of malignant pulmonary tumors in children are called bronchial adenomas, and although not benign, as the term implies, they are predominantly low grade in behavior. They include carcinoid tumor, mucoepidermoid carcinoma, and adenocystic carcinoma. Although pulmonary carcinoid tumors account for only 2% of all primary lung tumors in adults, between 40% and 85% of pediatric malignant lung lesions are carcinoids.[94-97] See "Carcinoid" for a more complete description of carcinoid and its management. Mucoepidermoid carcinomas (MECs)[98] and adenoid cystic carcinomas[99] are more often seen in the head and neck but can arise from mucous glands located in the respiratory submucosa.

Most bronchial adenomas are endobronchial; patients often have recurrent infections or obstructive pneumonitis before their diagnosis is determined (Fig. 65-4), and the most common presenting symptoms are cough, fever, or wheezing.[100-102] Although over 25% of adults with pulmonary carcinoid and MEC are asymptomatic, the figure is lower in children, who are less likely to have a radiographic study that would detect an incidental lesion.[103] Aggressive lesions can present with hemoptysis, chest pain, or pneumothorax in rare cases. It is extremely rare for patients with pulmonary carcinoid to show evidence of carcinoid syndrome in the absence of metastatic disease,[103] but a reported 2% to 4% of patients have Cushing syndrome.[101,104,105] A mass is usually detected by chest x-ray or chest CT, but endobronchial lesions may only be suspected by recurrent localized obstruction and volume loss (Fig. 65-5, *A* and *B*). Octreotide scans have a sensitivity of 80% to 90% for carcinoids and can be useful at diagnosis to assess for metastatic disease.[106] More recently, PET CT imaging with the somatostatin analog ^{68}Ga-DOTATOC has shown sensitivity of 97% and specificity of 92% in identifying neuroendocrine tumors.[107] Diagnostic biopsy is usually obtained by flexible fiberoptic bronchoscopy (see Fig. 65-5, *C*). Lymph nodes can be involved, especially with higher grade tumors, but may also be enlarged as a reaction to obstructive pneumonitis rather than tumor.

The typical carcinoid tumor and low-grade MEC are pathologically bland and have a low rate of postresection recurrence or metastasis, even with local invasion.[95] The rarer atypical carcinoids and high-grade MEC have a higher mitotic rate and more necrosis and are more likely to behave aggressively.[97,108] The appropriate therapy is open resection of tumor and involved lymph node, the extent of which is determined by the centrality of the mass. Lobectomy or even pneumonectomy may be required for tumors of the main stem bronchus. Because adenoid cystic carcinomas can spread submucosally with circumferential bronchial involvement, the margin of resection should be determined intraoperatively by frozen sections of the bronchial margins.[94] Local recurrences of bronchial adenomas can occur, especially for MECs, but metastases are rare. Adenoid cystic carcinoma has a greater likelihood of distant metastases than MECs and a poorer overall survival rate.[94] Estimates for metastases from bronchial carcinoid range from 5% to 27%.[101,109,110]

When surgery is not curative, other therapies can be used but have shown limited success.[111] Octreotide, a somatostatin analogue used to treat the symptoms of carcinoid syndrome, has been known to stabilize carcinoid tumor growth but not result in regression; similarly, interferon has been used with a modest response. Radionuclide therapy with radiolabelled somatostatin analogs have also been investigated for carcinoids in adults and have demonstrated control of disease and symptom improvement in patients with metastatic disease.[112]

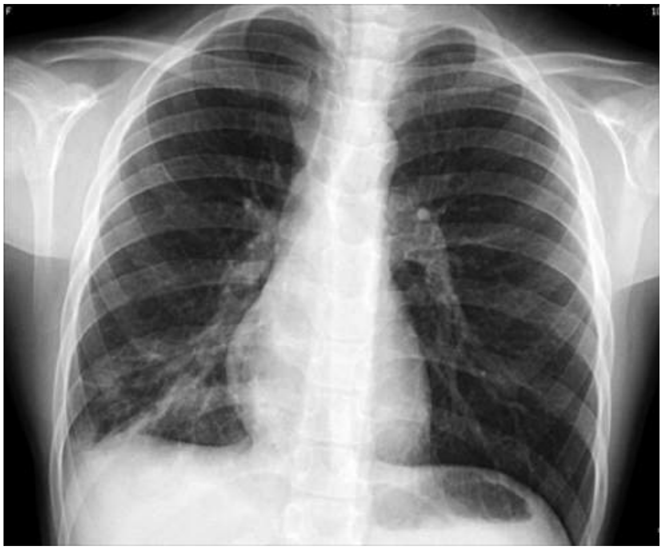

Figure 65-4 Plain radiograph of 9-year-old patient showing right lower-lobe infiltrate persistent over 1 month. Further workup revealed a right lower-lobe bronchus mucoepidermoid carcinoma.

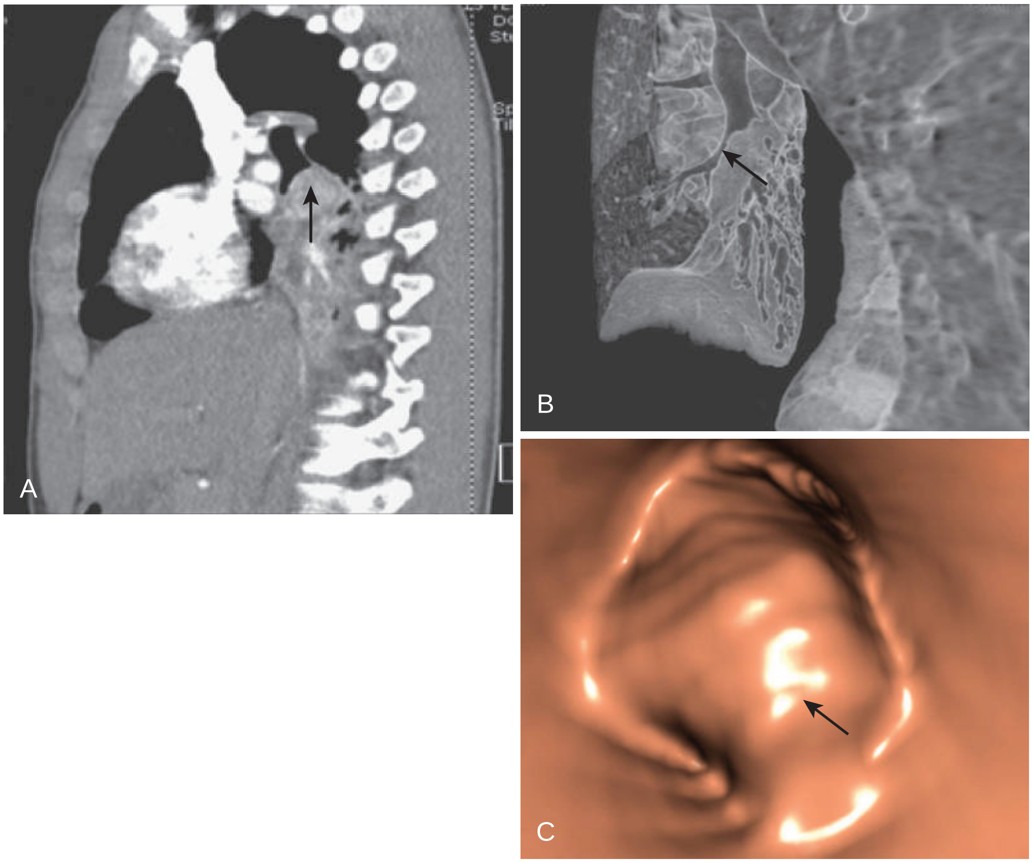

Figure 65-5 **A,** Carcinoid tumor *(arrow)* obstructing bronchus intermedius and causing peripheral consolidation of lung. **B,** Carcinoid tumor obstructing bronchus intermedius *(arrow)*. **C,** Carcinoid tumor *(arrow)* obstructing bronchus intermedius.

Cytotoxic chemotherapy for carcinoid and MECs has been used, but response rates, even with combination agents, are under 20%.[97,111] Novel molecular agents are being tested, including agents directed against VEGF, PDGFR, and mammalian target of rapamycin (mTor). Prognosis remains excellent for bronchial adenomas, even for locally invasive or high-grade tumors.

Pleuropulmonary Blastoma

Pleuropulmonary blastoma (PPB) in young children is distinct from pulmonary blastoma in adults; the pediatric tumor is composed of primitive blastema and neoplastic mesenchymal cells without epithelial malignant cells.[94,113] Since its initial description, there has appeared to be an increase in malformations and cancer in the afflicted child and family (Fig. 65-6).[114] Many pleuropulmonary blastomas are now known to be a part of a spectrum of dysplastic and neoplastic lesions that can arise from a constitutional mutation in *DICER1,* which is located on chromosome 14q and encodes a ribonuclease (RNase) endonuclease essential in the production of micro–ribonucleic acids (miRs). Other lesions that may arise as a result of germline *DICER1* mutations include ovarian sex-cord stromal tumors, cystic nephroma, embryonal rhabdomyosarcoma, ciliary body medulloepithelioma, nasal chondromesenchymal hamartoma, and multinodular goiter.[115-117] The tumor is located peripherally and can be locally invasive. Most patients have symptoms of wheezing, respiratory distress, or pneumothorax. Pathologically there are three subtypes: type 1 PPB, which is exclusively cystic, without a macroscopically detectable solid component); type 2 PPB with solid and true cystic areas; and type 3 PPB, a true solid tumor.[113] PPBs (particularly type 1 cystic lesions) are often misdiagnosed as congenital pulmonary airway malformations (CPAMs) because of similar appearance on chest x-ray and CT imaging. Echocardiography may occasionally demonstrate extension into the thoracic great vessels and heart, and fatal embolic events have been reported in rare occurrences.[118]

Treatment involves resection. Adjuvant chemotherapy (doxorubicin, actinomycin, vincristine, and cyclophosphamide or ifosfamide), especially for types 2 and 3, may reduce the risk of recurrence[119] or can be used neoadjuvantly to improve the resectability of large lesions.[120] Radiation has been used adjuvantly or palliatively; its role is unclear. If left unresected, type 1 lesions may eventually progress to more aggressive subtypes with development of anaplasia. Prognosis correlates with subtype; type 1 PPB that is completely resected has a 5-year survival rate of 85% to 90%, whereas type 2 and 3 tumors have 45% to 60% survival rates.[121,122] Metastases can develop in up to 55% of patients with type 3 PPB; the most common sites are the brain and spinal cord and

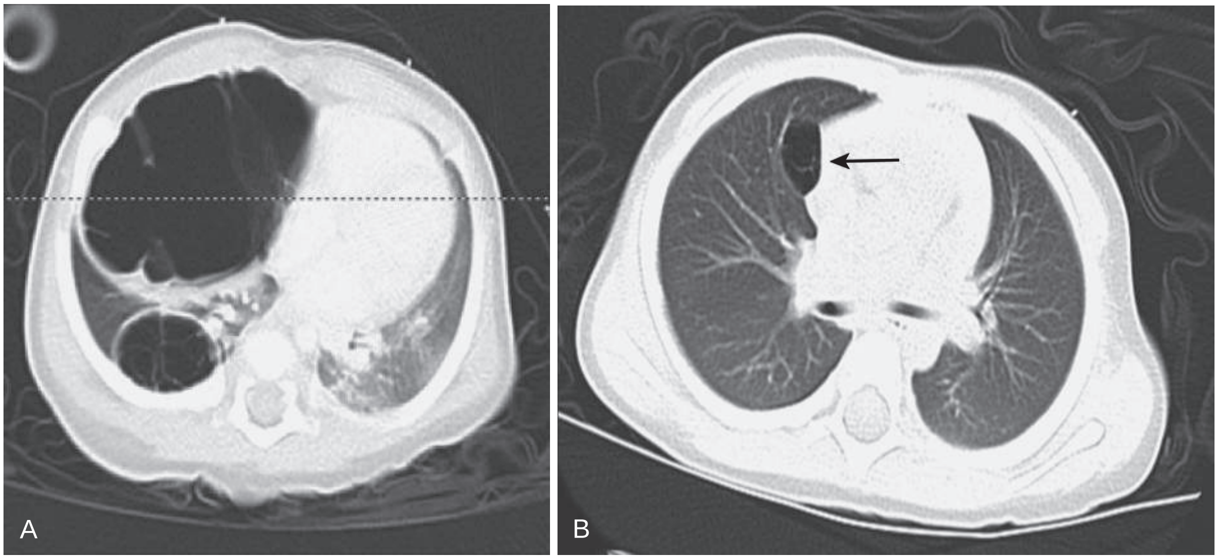

Figure 65-6 **A,** Two cystic lesions in 3-month-old infant found to be pleuropulmonary blastoma (PPB) on resection. **B,** Brother of patient with PPB in **A** with a benign cystic-adenomatoid carcinoma malformation *(arrow)*.

bone.[119,123] An international PPB registry has been established that collects clinical data on incident cases in an attempt to define the outcomes of patients with this rare disease. Families should be referred for genetic counseling to evaluate for the presence of a *DICER1* predisposition syndrome and risk of developing other related lesions.

Bronchogenic Carcinoma

Primary epithelial cancers of the lung are rarely seen in children; fewer than 100 cases have been reported in the literature. They are pathologically indistinguishable from the same tumors occurring in adults. Therapy should be planned after consultation with a medical oncologist experienced with lung cancers and in general should mimic the standard of care for adult tumors. When these histologies occur in children, they are often metastatic at diagnosis and have an aggressive course, high mortality, and average survival time of 7 months after diagnosis (Fig. 65-7).[94,97] Bronchioalveolar carcinoma (BAC) is a histology that accounts for less than 10% of lung malignancies in adults, with a mean age of presentation between the sixth and seventh decades. In children, mucinous BAC has been associated with CPAM type 1[94,124,125] and has also been reported as a second malignancy in osteosarcoma survivors.[126] Surgery is the primary treatment for BAC. Prognosis depends on nodal status and the resectability of the tumor; it appears to be slightly better for children than for adults with BAC or for children with other primary bronchogenic carcinomas.[127] Squamous cell carcinoma,[128] adenocarcinoma,[97] and small-cell lung cancer[129,130] are occasionally seen in children.[100] There is no clear causative pathway or association with environmental exposure, and most patients have no family history to suggest a genetic component. A rare form of adenocarcinoma in children is well-differentiated fetal adenocarcinoma (WDFA), which histologically resembles fetal lung and has an excellent prognosis.[97,131,132]

Other Pulmonary Tumors

Sarcomas arise from mesenchymal cells and therefore can develop from connective tissue cells in the lung. The most common types seen are hemangiopericytoma, synovial sarcoma, leiomyosarcoma, bronchopulmonary fibrosarcoma, and rhabdomyosarcoma.[94,100] Ewing sarcoma—peripheral primitive neuroectodermal tumor in the lung (Askin tumor)—is often pleural-based. Given its marked chemosensitivity, it should be treated with chemotherapy

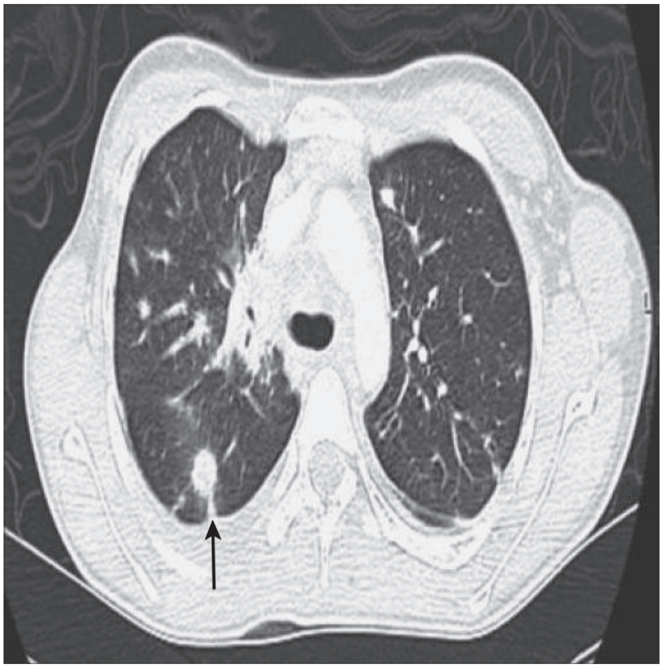

Figure 65-7 A 14-year-old patient with primary pulmonary poorly differentiated carcinoma *(arrow)* and lung, bone, lymphatic, hepatic, and adrenal metastases.

before surgical resection in contrast to almost all other lung tumors (see Chapter 61). Pleural mesothelioma is occasionally seen in children, with fewer than 100 cases in the literature and even fewer that have been confirmed by pathologic review.[133] Although there have been reports of assumed causation by asbestos exposure and chemotherapy and/or radiation for another malignancy, most cases appear in healthy children.[133,134] The tumor is similar to that in adult cases in its pathologic appearance and poor prognosis, with a median survival length of approximately 10 months.[135,136] Most cases are treated with a multimodality approach, but tumors are often diffuse and unresectable and are poorly responsive to chemotherapy and radiation. Current concepts in the therapeutic approach of adults with mesothelioma include the use of cisplatin and multitargeted antifolate chemotherapy[137] and aggressive surgery (extrapleural pneumonectomies).[138]

GASTROINTESTINAL STROMAL TUMORS

Epidemiology

Gastrointestinal stromal tumors (GISTs) are the most common mesenchymal neoplasm of the gastrointestinal tract in adults, with an incidence of 11 to 19.6 cases per million, which translates into 3300 to 6000 new cases per year.[139-141] GISTs are presumed to originate from the interstitial cells of Cajal, which regulate gastrointestinal motility.[142] Bardsley has characterized a putative interstitial cell of Cajal stem cell. This cell is capable of self-renewal and differentiation, has a KIT$^{\text{low}}$CD44+CD34+ phenotype, and is not dependent on KIT signaling for survival and proliferation.[143]

Gastrointestinal Stromal Tumors in Adults

The median age at diagnosis of GIST is approximately 60 years, and the disease has no sex predilection.[141,142] The most common presenting symptoms are abdominal pain, palpable mass, and gastrointestinal bleeding.[144] In adults, tumors range in size from 1 to 40 cm with a median size of 5 cm and most commonly arise in the stomach (60%) followed by the small intestine (30%) colon, rectum (5%), and esophagus (5%). About 95% of GISTs stain positive for CD117, and activating mutations of *KIT* (70% to 80%) and *PDGFRα* (~7%) are seen in nearly 90% of adult GISTs. About 12% to 15% of adult GISTs are wild-type for *KIT* and *PDGFR*, but mutations of other genes such as *BRAF, SDHB, KRAS,* and *NRAS* have been increasingly recognized (Table 65-5).[144]

Chemotherapy for unresectable or metastatic GISTs produces responses in fewer than 10% of patients, and the median survival for adults with metastatic disease is historically 20%.[145] The use of the tyrosine kinase inhibitor imatinib has revolutionized the treatment of GIST. Administration of this drug to adults with unresectable or metastatic GISTs produce responses in up to 85% of patients, and the median survival time for this group has increased to 58 months.[146] The likelihood of response to imatinib is correlated with the mutational genotype of the tumor; patients with *KIT* exon 11 mutations have significantly higher response rates to imatinib than patients with exon 9 mutations or no mutations.[147] A similar pattern has been documented for patients with *PDGFR* mutations; two thirds of patients with *PDGFR* lesions have the imatinib-resistant isoform D842V.[148] Suggested initial management of GISTs based on mutational status is shown in Table 65-5.

TABLE 65-5 Genetic Subtypes and Use of Imatinib in Selected Subsets of Adult Gastrointestinal Stromal Tumors

Genetic Type	Frequency of Total	Adjuvant Imatinib	Imatinib for Metastatic Disease
KIT mutated	80%		
Exon 11	67%	Yes, 400 mg/d	Yes, 400 mg/day
Exon 9	10%	Yes, 400 mg/day	Yes, 800 mg/day
Other	2%	Yes, 400 mg/day	Yes, 400 mg/day
PDGFR mutated			
Exon 12	5% to 8%		
Exon 14	1%	Yes, 400 mg/day	Yes, 400 mg/day
Exon 18	<1%	Yes, 400 mg/day	Yes, 400 mg/day
D842V	5%	No	No
Wild-type	12% to 15%		
BRAF V600	7% to 15%	?	?
SDH A,B,C,D	2%	?	?
HRAS/ NRAS	<1%	?	?
Other	2%	?	?

Pediatric Gastrointestinal Stromal Tumors and Succinate Dehydrogenase–Deficient Gastrointestinal Stromal Tumors

Epidemiology and Presenting Features

Pediatric GISTs account for 1% to 2% of all GISTs, but their true incidence in the United States is largely unknown.[149,150] Review of the SEER database from 2000 through 2009 revealed 23 cases of malignant GIST, and 14 were seen in patients between 15 and 19 years of age for an expected incidence of 0.06 per million among this age group. In children and adolescents these tumors present at a median age of 14 years and predominantly affect females. The most common presenting symptoms are gastrointestinal bleeding, abdominal pain, anemia, weight loss, vomiting and early satiety. About 20% of patients have metastatic disease at diagnosis, and approximately 10% have a history of Carney triad or Carney Stratakis syndrome (see below).[151,152,153] GISTs in younger patients more commonly arise in the stomach, tend to be multifocal and involve lymph nodes, more often contain epithelioid or mixed histology, and have a more indolent clinical course. Despite surgical resections, 30% to 80% of patients develop metastatic disease to lymph nodes, liver, or locoregional sites, but despite multiple recurrences, survival is close to 90%.[154]

Biology

In children and adolescents, GISTs can occur within the context of two genetic syndromes: Carney triad and Carney Stratakis syndrome.[155,156] Carney triad is characterized by pulmonary chondroma, GIST, and paraganglioma, whereas Carney Stratakis syndrome lacks the pulmonary chondromas. Furthermore, Carney triad is sporadic and its cause is not known, whereas Carney Stratakis syndrome is caused by germline inactivating mutations of succinate dehydrogenase (SDH) B, C, or D.[157] Unlike adult GIST in which *KIT* and *PDGFR* mutations are key for disease development, only about 15% of GIST tumors found in children have activating mutations of one of these two genes. Despite this their tumors still express *KIT* at comparable levels to those seen in adults.[151,158] In contrast to adult GISTs, pediatric tumors lack large-scale chromosomal or genomic aberrations and overexpress *IGF1R*, suggesting that this pathway should be investigated as a possible therapeutic target in these patients.[150,158-160]

About 10% of children with wild-type GIST and no history of paraganglioma have a heterozygous germline mutation of SDH B or C.[161] Additionally, wild-type GIST in patients under 20 years of age almost lack *SDHB* expression as determined by immunohistochemistry, and nearly 90% of SDHB-negative cases express *IGF1R* by immunohistochemistry.[162,163] *SDHD* germline mutations have been reported in cases of sporadic GIST and in association with familial paraganglioma.[157,164] Germline *SDHA* mutations have also been reported in sporadic GIST.[165] Interestingly, about 30% of SDHB-negative cases by immunohistochemistry also lack *SDHA* expression, and immunohistochemical loss is strongly associated with germline mutations of *SDHA*.[164] Given the markedly different biology of GIST in younger patients, some investigators prefer using the term *SDH-deficient GIST* to identify a preferentially younger population that has wild-type GIST and SDH-deficient driven tumors.

Treatment

GIST in younger patients has a more indolent course, and recurrences are common. For this reason, ultimate cure in this group of patients is unlikely and treatment options that combine the judicious use of surgery combined with selected medical therapies offer the best chance for disease control. Because of the rarity of this disease, it is recommended that children and adolescents with GIST be preferentially managed by a multidisciplinary team with expertise in sarcoma and gastrointestinal tumors.[166] Initial management of localized disease should include surgical resection with the goals of achieving a gross resection with an intact pseudocapsule and negative margins. Lymph-node sampling in younger patients should be considered. Gastrectomy and other extensive surgeries should be avoided, because recurrence is common; therefore wedge resections are preferred. The use of adjuvant imatinib in patients with wild-type high-risk tumors is not recommended. For patients with unresectable or metastatic disease who have a *KIT* or *PDGFR* mutation, treatment according to Table 65-5 or the National Comprehensive Cancer Network (NCCN) guidelines is recommended.[167] Wild-type or SDH-mutated GISTs do not usually respond to tyrosine kinase therapies used in adults, and in selected asymptomatic patients with active disease, careful observation and follow up care might offer the best approach. In patients who develop significant symptoms or progression, a trial of imatinib or sunitinib is warranted; in one series one partial response and five cases of disease stabilization were seen in children refractory to imatinib.[168] A trial using sunitinib in patients 6 to 21 years if age with wild-type GIST and a trial using the tyrosine kinase inhibitor directed against insulin-like growth factor 1 receptor (IGF1-R) OSI-906 in patients over 18 years with wild-type GIST are ongoing. Follow-up care should include imaging and examinations every 3 to 6 months for 5 years. The use of CT should be limited when possible, and use of MRI and plain chest radiographs encouraged.

CARCINOID TUMORS

Carcinoid tumors are tumors of neuroendocrine cells that derive from embryonic divisions of the gut. The most common locations for carcinoid tumors are in locations arising from the midgut: the appendix, small intestine, proximal colon, and rectum. Carcinoid tumor of the appendix is speculated to be the most common tumor of the gastrointestinal tract in children.[169] Tumors of the epithelial component of the bronchial mucosa arising from the foregut appear as carcinoid tumors of the lung and bronchus. Biologically, carcinoid tumor cells contain membrane-bound neurosecretory granules that contain hormones and biogenic amines. When serotonin, 5-hydroxyindole acetic acid (5-HIAA), and other metabolites of the granules are released, a syndrome of flushing, diarrhea, and abdominal cramps can occur. The syndrome rarely occurs in children, because it is associated with large tumor mass, hepatic metastases, or distant metastases.[170] Carcinoid tumors are one of the rarer tumors (less than 10%) seen in the autosomal dominant syndrome MEN type 1 (MEN1), which is caused by a mutation in the tumor suppressor gene *MEN1* located at 11q13.[171,172] *MEN1* may be involved in sporadic carcinoid tumors as well, as evidenced by loss of heterozygosity (LOH) on chromosome 11 or inactivated copies of the *MEN1* gene.[173,174] Other possible contributors may be p53, K-ras-2, C-raf-1, and Bax/Bcl2.[172]

In a review of a 22-year period at St. Jude Children's Research Hospital, 0.08% of patients evaluated for malignancy had carcinoid tumors.[175] In that series, like others, the majority (approximately 60%) arose in the appendix. Pathologic examination of appendectomy specimens reveal carcinoid tumors in 0.23%, with the figure slightly lower in children than adults (Fig. 65-8).[170] Most patients with appendiceal carcinoid tumors have

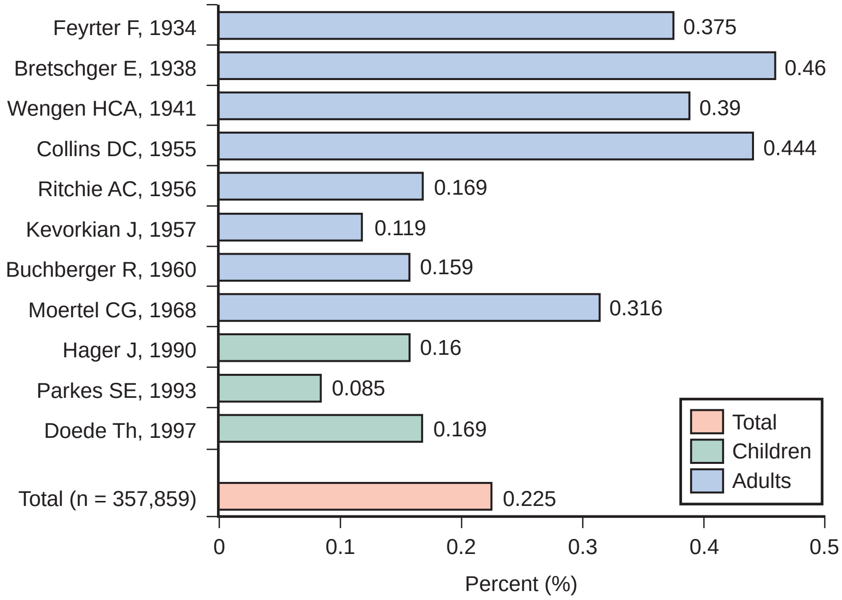

Figure 65-8 Percentage of appendectomy specimens found to have carcinoid tumors on pathologic examination. *(Modified from Doede T, Foss HD, Waldschmidt J: Carcinoid tumors of the appendix in children-epidemiology: clinical aspects and procedure.* Eur J Pediatr Surg *10:372–377, 2000.)*

symptoms of acute appendicitis; others have chronic abdominal pain, or an incidental appendectomy is done during another surgical procedure. The diagnosis is rarely made preoperatively.

Appendiceal carcinoid tumors smaller than 1 cm rarely metastasize, and appendectomy alone is the appropriate therapy.[176] After a diagnosis of an appendiceal carcinoid tumor, it is reasonable to check levels of serum serotonin and chromogranin A and 24-hour urinary 5-HIAA, and abdominal imaging should be performed to look for metastases. Octreotide scans have a sensitivity of 80% to 90% for carcinoid tumors and can be useful at diagnosis to assess for metastases,[106,177] although there is a low incidence of distant disease in children. For appendiceal tumors larger than 2 cm, right hemicolectomy is advocated in adults[178]; there is controversy regarding its use for tumors between 1 and 2 cm and for children, for whom cecal or ileocecal resection may suffice.[179-181] Additionally, there are only rare cases of carcinoid tumors of the appendix with perforation described, but it is presumed that perforation in any carcinoid tumor would increase the risk for dissemination. The decision for hemicolectomy, particularly in those children with tumors having some high-risk features but size between 1 and 2 cm, must be made on a case-by-case basis.[182]

No deaths from pediatric appendiceal carcinoid have been reported in several large series with extended follow-up study.[169,180,181] In addition to increasing size, location at the base of the appendix and the presence of mucin-producing cells are thought to be poor prognostic indicators.[178] Given its rarity and benign behavior, recommended follow-up care is controversial. Several authors have recommended a schedule of monitoring serotonin metabolites, with or without abdominal ultrasonography, in patients whose tumor diameter was more than 5 mm.[170,176] The findings that 14.6% of patients with appendiceal carcinoids in the SEER registry had synchronous or metachronous noncarcinoid malignant tumors,[183] that the risk of offspring carcinoid tumors (SIR 4.31) and secondary cancers (standardized incidence ratios [SIR] 2.15-3.31) was elevated in a Swedish registry study,[184] and several case reports of patients with secondary adenocarcinoma of the colon[175,185,186] have raised other questions of appropriate counseling and follow-up care for these patients. For the rare metastatic carcinoid tumor in childhood, treatment recommendations are based on experience in adult patients. Octreotide, a somatostatin analogue that has been used to treat the symptoms of carcinoid syndrome, has stabilized carcinoid tumor growth but not resulted in regression.[187] Similarly, interferon has been used with a modest response.[188] Recent efforts have demonstrated possible clinical activity of mTOR inhibitors and certain receptor tyrosine kinase inhibitors, but these initial findings await more follow up investigation and larger studies.[189]

COLORECTAL CARCINOMA

In Western and developed countries, colorectal carcinoma is one of the most common malignant cancers and is responsible for significant morbidity and mortality. Conversely, colorectal carcinoma is rare in populations that do not have high rates of obesity and meat consumption. In the United States alone, approximately 153,000 patients per year are diagnosed with colorectal carcinoma, and approximately 52,000 deaths each year are attributed to it.[190] However, colorectal carcinoma is rare in children, with fewer than 100 cases per year in the United States as estimated by SEER data and approximately one case per million in those younger than age 20

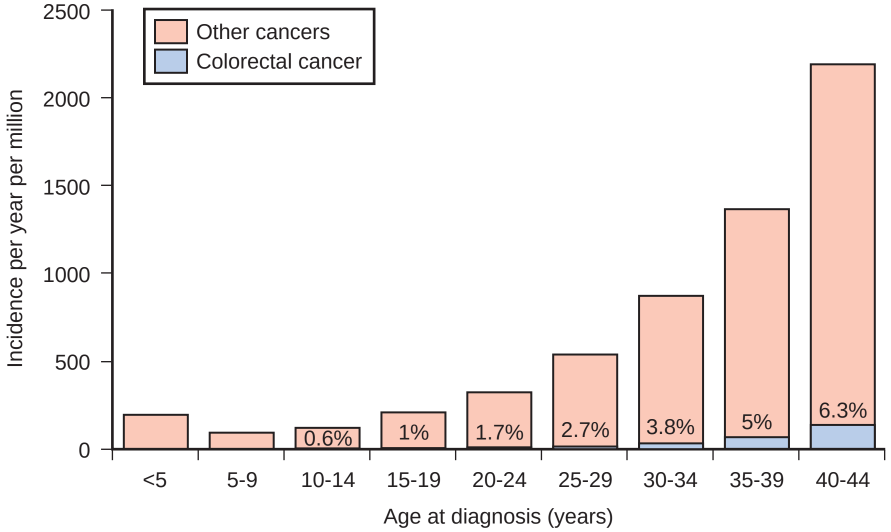

Figure 65-9 Incidence of colorectal cancer relative to all cancer, SEER 1975-2000. *(Data from Bleyer A, O'Leary M, Barr R, Ries LAG, editors:* Cancer epidemiology in older adolescents and young adults 15 to 29 years of age, including SEER incidence and survival: 1975-2000 [NIH Publication No. 06-5767]. *Bethesda, Md., 2006, National Cancer Institute.)*

years. The incidence of colorectal carcinoma relative to other cancers by age is shown in Figure 65-9, the 5-year survival rates of colorectal carcinoma by age are shown in Figure 65-10, and 5-year survival rates by age and stage are shown in Figure 65-11. Although case series offer suggestions about the biologic nature of this tumor in patients younger than 20 years, the rarity of this diagnosis in children means that comprehensive population-wide data are not available. Any case series from a large institution will be limited in number and by referral bias. Although many case series have suggested a higher stage at diagnosis for pediatric colorectal carcinoma and a prevalence of mucinous histology,[191,192] SEER data suggest that this disease in children more closely mirrors the adult presentation and that referral bias could lead to the findings in the case series.

Most cases of colorectal carcinoma in adults occur sporadically and in association with lifestyle choices. Only approximately 10% of adults with colorectal carcinoma have an identified inherited or acquired predisposition to it. These include patients with the dominantly inherited FAP syndrome who have a mutation in the *FAP* tumor suppressor gene, patients with Lynch syndrome (also known as hereditary nonpolyposis colorectal cancer [HNPCC]) characterized by one of several defects in DNA mismatch repair genes, or patients with long-standing inflammatory bowel disease of more than 10 years' duration. It is not clear from the data whether

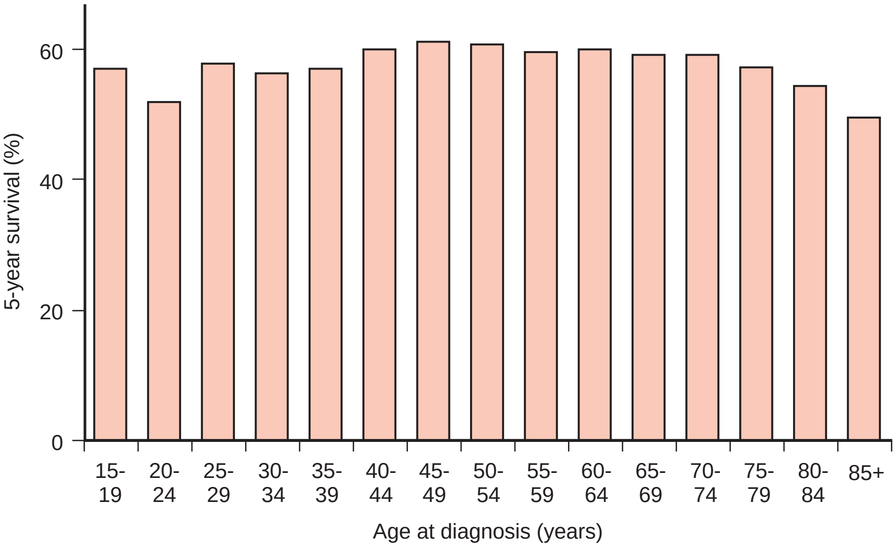

Figure 65-10 5-year survival rate for colorectal carcinoma, SEER 1975-1999. *(Data from Bleyer A, O'Leary M, Barr R, Ries LAG, editors:* Cancer epidemiology in older adolescents and young adults 15 to 29 years of age, including SEER incidence and survival: 1975-2000 [NIH Publication No. 06-5767]. *Bethesda, Md., 2006, National Cancer Institute.)*

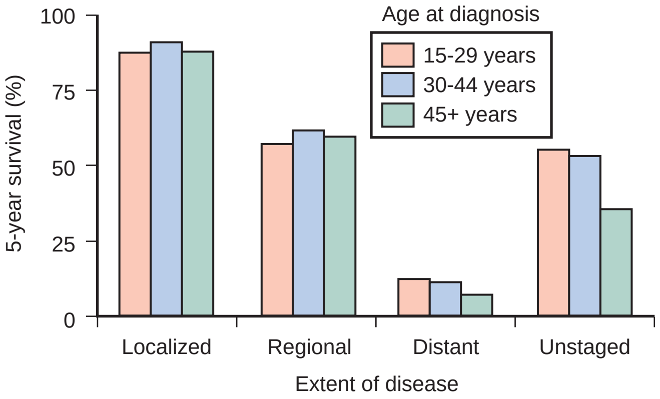

Figure 65-11 5-year survival rate for colorectal cancer by extent of disease, SEER 1975-2000. *(Data from Bleyer A, O'Leary M, Barr R, Ries LAG, editors:* Cancer epidemiology in older adolescents and young adults 15 to 29 years of age, including SEER incidence and survival: 1975-2000 [NIH Publication No. 06-5767]. *Bethesda, Md., 2006, National Cancer Institute.)*

children diagnosed with colorectal carcinoma are likely to have one of these common predispositions to the disease or if there is some other causative factor in these patients. Children with FAP, also known as Gardner syndrome, are commonly found to have myriad polyps on colonoscopy and many ultimately undergo prophylactic total colectomy before the age of 21 years because of symptoms (e.g., continued blood loss) or because of a strong family history of colon cancer. The vast majority of patients with FAP syndrome develop colorectal cancer by the age of 40 years. Many children who do undergo prophylactic colectomy are found to have dysplasia that was not apparent on routine screening colonoscopy.[193] Prophylactic colectomy is not clearly indicated in patients with Lynch syndrome, although in cases where there is lack of compliance with routine colonoscopy it may be appropriate.[194] Other syndromes associated with colorectal carcinoma include Bloom, Peutz-Jeghers, Turcot, Oldfield, and Rendu-Osler-Weber syndromes.[195-199]

Clinical Presentation

Colorectal carcinoma arises from the mucosal surface of the bowel, often growing from within a polyp. The tumor can cause intestinal obstruction through growth into the lumen of the bowel or can erode through the serosa and spread intraperitoneally. The early signs of colorectal carcinoma are difficult to separate from more common causes of abdominal complaints. Anemia, vague abdominal pain, bleeding, weight loss, and change in bowel habits have all been reported as the presenting complaint for children with colon cancer.[191] Many of these presenting complaints are common in pediatric care; it is possible that children who seek care with higher stages of colon cancer would have earlier diagnoses if they were adults, because an older adult with these complaints would likely be referred for colonoscopy. In two relatively large series reporting on this rare tumor in children, 0 of 20 and 3 of 30 patients had modified Dukes stage B tumors.[191-192] All other patients were stage C or D, and only 1 of 20 and 2 of 30 patients were alive without evidence of disease when these reports were published. In these two series, 16 of 20 and 25 of 30 patients had tumors with mucinous histology, a higher rate than that reported for adults with colorectal carcinoma. Again, these dire statistics likely reflect referral patterns, although they demonstrate that children with colorectal carcinoma can have high-stage disease at diagnosis. Although vigilance for pediatric colorectal carcinoma remains important, in the absence of known risk factors for the disease, adult-oriented screening examinations such as colonoscopy, routine testing of stool for occult blood, and sigmoidoscopy are not indicated, because they would pick up many false-positives and would not be cost-effective.

Diagnosis and Staging

The diagnosis of colorectal carcinoma in children requires a high index of suspicion in patients with the typical presenting signs or symptoms and tissue acquisition. The exact procedure required to obtain tissue for diagnosis is best determined in consultation with surgical colleagues and depends on the patient's clinical situation. For some patients, complete resection before chemotherapy may be appropriate, but for others, particularly those known to have metastatic disease, chemotherapy or radiotherapy may make resection possible in previously unresectable cases, so a less invasive approach to diagnosis is warranted after careful consultation with a multidisciplinary team. Any patient undergoing resection should have up to 12 lymph nodes sampled in an attempt to determine whether the cancer has spread.[200] An expert panel convened by the American Society of Clinical Oncology has not recommended adjuvant chemotherapy for those adult patients with stage II colorectal carcinoma that can be fully surgically resected. Children tend to have more widespread disease at presentation; however in the absence of data to support a contrary approach, for children with disease that can be fully resected at initial diagnosis, surgical intervention and subsequent observation seem to be indicated.[201]

For pediatric patients discovered to have colorectal carcinoma, full staging should involve functional and anatomic imaging (see later) as would be carried out in adult patients. In adults, linked PET and CT scans are increasingly becoming the norm, because this modality helps link fluorodeoxyglucose (FDG)-avid lesions with actual sites of disease more efficaciously than separate PET and CT scans that cannot be linked because of bowel movement. Most large pediatric oncology centers now have access to linked PET and CT. Barium enema is sometimes used to help identify areas of concern before the diagnosis is made, and a bone scan can be used to identify bone metastases if there is concern that PET is not picking up lesions.[202] The AJCC staging for colorectal carcinoma is shown in Tables 65-6 and 65-7.

Treatment

Initial management of the patient is focused on the diagnostic and staging workup and on any surgical interventions that are urgently needed in the context of bowel-related emergencies such as perforation or obstruction. Consultation with medical oncologists experienced

TABLE 65-6 Tumor-Nodes-Metastasis Definitions for Colorectal Carcinoma

Primary Tumor (T)	Regional Lymph Nodes (N)[§]	Distant Metastasis (M)
TX: Primary tumor cannot be assessed T0: No evidence of primary tumor Tis: Carcinoma in situ: intraepithelial or invasion of the lamina propria[*] T1: Tumor invades submucosa T2: Tumor invades muscularis propria T3: Tumor invades through the muscularis propria into the subserosa or into nonperitonealized pericolic or perirectal tissues T4: Tumor directly invades other organs or structures and/or perforates visceral peritoneum[†,‡]	NX: Regional nodes cannot be assessed N0: No regional lymph node metastasis N1: Metastasis in one to three regional lymph nodes N2: Metastasis in four or more regional lymph nodes	MX: Distant metastasis cannot be assessed M0: No distant metastasis M1: Distant metastasis

From Colon and rectum. In Edge SB, Byrd DR, Compton CC, et al, editors: AJCC cancer staging manual, *ed 7, New York, 2010, Springer, p. 143–164.*

[*] Tis includes cancer cells confined within the glandular basement membrane (intraepithelial) or lamina propria (intramucosal) with no extension through the muscularis mucosae into the submucosa.

[†] Direct invasion in T4 includes invasion of other segments of the colorectum by way of the serosa; for example, invasion of the sigmoid colon by a carcinoma of the cecum.

[‡] Tumor that is adherent macroscopically to other organs or structures is classified T4. If no tumor is present in the adhesion microscopically, however, the classification should be pT3. The V and L substaging should be used to identify the presence or absence of vascular or lymphatic invasion.

[§] A tumor nodule in the pericolorectal adipose tissue of a primary carcinoma without histologic evidence of residual lymph node in the nodule is classified in the pN category as a regional lymph node metastasis if the nodule has the form and smooth contour of a lymph node. If the nodule has an irregular contour, it should be classified in the T category and also coded as V1 (microscopic venous invasion) or as V2 (if it was grossly evident), because there is a strong likelihood that it represents venous invasion.

in evaluating adult patients with colorectal carcinoma may help guide the workup.[203] Because of the potential for anemia from bleeding and liver involvement, as well as the potential for peritoneal seeding, complete blood counts, liver function tests, and kidney function tests with electrolyte levels should be obtained at diagnosis.[191] Carcinoembryonic antigen (CEA) should also be determined, although most series have found that children tend not to have heightened CEA at diagnosis,[191-192] and subsequently followed to survey for occult recurrence. Many chemotherapeutic agents can increase CEA, so care should be taken when interpreting these values, especially when the patient is receiving oxaliplatin.[204] These patients should generally not have values checked until they have recovered from chemotherapy. If the patient did not have an elevated CEA level at diagnosis, the decision not to monitor subsequent levels to screen for occult relapse is reasonable but should be made in close consultation with medical oncology colleagues.

The treatment for children with colorectal carcinoma should be planned in conjunction with reports in the adult literature and with a medical oncologist experienced in treating gastrointestinal cancer in adults. Adult patients with stage II disease have not been shown to benefit from adjuvant chemotherapy if they have no evidence of disease after resection[201] and should undergo wide surgical resection with anastomosis if possible. It is reasonable to recommend careful observation after surgical treatment for children in this scenario in the absence of a clinical trial, because there is no standard of care therapy for these patients that has proven to reduce the risk for relapse. Although these patients should be considered for randomized controlled clinical trials, there are likely to be few trials available that include children younger than 18 years. If details of the case or of the surgical resection increase the concern that the patient could suffer a relapse, adjuvant therapy could be considered because the risk for recurrence could be from 51% to 73%.[205] The situation should include careful discussion between the oncologist and family. For patients with stage III or higher disease, chemotherapy has demonstrated a survival benefit for adults with colorectal carcinoma, and children should be treated in a similar fashion.[206] Patients with metastatic colorectal carcinoma should have their tumors tested for *KRAS* in codons

12 or 13 in a Clinical Laboratory Improvement Amendment (CLIA)–certified laboratory. Those with tumors demonstrated to have *KRAS* mutations should not receive anti–epidermal growth factor receptor (EGFR) antibody therapy with chemotherapy, because it is not of benefit in these cases in adults.[207]

SEER data have suggested that the proportion of children with colorectal carcinoma who have high-stage disease at diagnosis mirrors that of adults with colorectal carcinoma. Thus at diagnosis many children have a higher stage disease that is fully resectable and that requires chemotherapy. These patients tend to have a poor prognosis. There are several regimens associated with prolonged survival for patients with metastatic colorectal carcinoma in adults based on the use of 5-fluorouracil (5-FU), oxaliplatin, and irinotecan in a variety of combinations. Bevacizumab (Avastin) is also being used in conjunction with these regimens, often as second-line therapy in adults, with the benefit of an improvement in survival.[208] Children with high-stage colorectal carcinoma have a poor prognosis, and any child successfully cured may have years of life added, so it may be reasonable for pediatric oncologists to add bevacizumab to the established regimens as frontline therapy. However, this depends somewhat on the clinical scenario. Bevacizumab has been tested in children with cancer in combination therapy, and a pediatric phase I trial of bevacizumab has been completed, so there is experience administering this agent to children.[209] New data also suggest that blocking VEGF with aflibercept has therapeutic benefit in colorectal carcinoma.[210] Further information on chemotherapy regimens for patients with colorectal carcinoma can be found at http://www.cancer.gov/cancertopics/pdq/treatment/colon/HealthProfessional/page4.

Screening and Preventive Therapy for At-Risk Children

Children with a family history of FAP syndrome should generally begin undergoing colonoscopy by the age of 10 or 12 years and should be observed closely by geneticists and pediatric gastroenterologists.[211,212] For such patients, prophylactic colectomy is essential to prevent death from colorectal carcinoma later in life. The decision to undergo total colectomy must be made in conjunction with the family history and timing of cancer onset in the pedigree, the clinical situation, and the child's wishes. Patients with HNPCC are unlikely to develop colorectal carcinoma before the age of 18 years, but the accepted standard for such patients is to begin regular colonoscopy at 20 years of age or at least 10 years earlier than the earliest onset of colorectal carcinoma in their pedigree.[213] For patients with inflammatory bowel disease, care should be based on standard practices for pediatric gastroenterology. Cyclooxygenase-2 (COX-2) inhibitors have been shown to reduce the risk for developing colorectal carcinoma in adults but are known to increase the risk for cardiovascular side effects, so they are not universally recommended for adults at risk of developing colorectal carcinoma.[214] These agents have been used in the pediatric oncology setting and may in the future be appropriate chemoprophylaxis for children at high risk for colorectal carcinoma.[215]

Follow-Up Observation

For the child with the sporadic occurrence of colorectal carcinoma who is cured by surgery or surgery and chemotherapy, careful observation must be recommended. However, there is little evidence available on the risk for such children to suffer recurrence or the risk for second malignancies later in life. Colorectal carcinoma is rare in children and often difficult to cure, so survivors are few. No large-scale randomized trials have documented the efficacy of a standard, postoperative monitoring program in adults to date. Therefore given the long latency period for relapse for young children, they should probably be screened with regular colonoscopy and radiologic evaluation of the lungs and perhaps PET scanning as well.[216,217] Because pediatric colorectal carcinoma is so rare, the child may suffer from a cancer predisposition syndrome and consideration should be given to such a diagnosis. The child may benefit from yearly colonoscopy and should be brought to medical attention with little delay for any blood in the stool or other symptoms of colon cancer. Screening for CEA at a reasonable interval could be considered but is associated with a high rate of false-positives in adults. It should probably only be used for children who had high levels at presentation and are healthy enough to undergo risky surgery if any liver or lung metastases are found early by screening.[216] Although the 5-year survival rate for low-stage colon cancer is excellent (approximately 90%), patients with metastatic disease have less than a 10% 5-year survival rate. For those who survive metastatic pediatric colorectal cancer, it is unclear for how long surveillance against relapse should be done, but follow-up care in a long-term survivor clinic is indicated.

URINARY BLADDER CARCINOMA

Rhabdomyosarcoma is a relatively common tumor affecting the urinary tract and is discussed elsewhere in this text (see Chapter 59). Malignant epithelial tumors of the bladder are extremely rare in children in the Western world; the incidence of bladder cancer in general is higher in Africa because of the inflammation caused by chronic parasitic infection with bilharzial and other organisms.[218] Boys are more likely than girls to be diagnosed with this.[219] The presenting signs and symptoms of transitional cell tumors of the bladder in children include gross painless hematuria, urinary tract infections, voiding difficulties, and even hematospermia.

If a child is suspected of having a bladder tumor, the differential diagnosis must include malignancies such as epithelial bladder cancer and rhabdomyosarcoma, as well as benign lesions such as inflammatory masses. In the absence of obvious clinical signs of a mass, these patients are usually seen first by the pediatric urologist. The initial workup should include urinalysis and culture, urine cytology, and imaging studies. CT or MRI can help define the lesion. Cystoscopy can help reveal the nature of the tumor and allow for biopsy of lesional tissue. Attempts at transurethral biopsy are a primary mode of obtaining a tissue diagnosis, with open procedures to be considered

as a backup maneuver.[220] Because bladder cancer is uncommon in younger patients, delay in diagnosis is not uncommon for younger patients. However, the outcome for children and young adults with bladder carcinoma seems to be better than for adults, explained in part by more indolent clinical and biological features. Patient younger than 20 years of age at diagnosis, for instance, have a lower incidence of chromosome 9 abnormalities, *FGFR3* mutations, and few epigenetic alterations. Therefore treatment decisions must include careful consideration of late effects.[221]

OVARIAN TUMORS

Approximately 50% of tumors occurring in the ovary in children are nonneoplastic. Furthermore, the minority of neoplastic lesions are malignant, so that only 10% to 20% of ovarian masses in children are cancerous (Box 65-1).[222-224] In children and even in adolescents, surgical management plans should take into consideration the lower rate of malignancy than in adults and minimize the risk of compromising hormonal function and fertility.[225] Ovarian masses usually present with abdominal pain, bloating, distention, or dysmenorrhea. The most appropriate and widely used initial evaluation tool for an ovarian mass is ultrasonography, which can distinguish the size, origin, and cystic nature of the tumor.[226] If cystic, unilateral, and presumed benign, a laparoscopic procedure is appropriate. Otherwise, further workup with chest, abdomen, and/or pelvic CT and tumor markers such as β-human chorionic gonadotropin (β-hCG), α-fetoprotein (AFP), cancer antigen-125 (CA-125), and CEA is required, and open laparotomy should be the surgical approach.[226] Ovarian tumors are staged by the International Federation of Gynecology and Obstetrics (FIGO) system (Table 65-8).

Of the neoplastic tumors, germ-cell tumors account for 65% to 70% (see Chapter 63). Epithelial carcinomas, the

TABLE 65-8 Carcinoma of the Ovary

Stage	Extent of Growth
I	Growth limited to the ovaries
IA	Growth limited to one ovary; no ascites present containing malignant cells; no tumor on the external surface; capsule intact
IB	Growth limited to both ovaries; no ascites present containing malignant cells; no tumor on the external surface; capsules intact
IC[*]	Tumor either stage IA or IB, but with tumor on surface of one or both ovaries or with capsule ruptured, ascites present containing malignant cells, or positive peritoneal washings
II	Growth involving one or both ovaries with pelvic extension
IIA	Extension and/or metastases to the uterus and/or tubes
IIB	Extension to other pelvic tissues
IIC[†]	Tumor either stage IIA or IIB, but with tumor on surface of one or both ovaries or with capsule(s) ruptured, ascites present containing malignant cells, or positive peritoneal washings
III	Tumor involving one or both ovaries, with histologically confirmed peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes; superficial live metastases equals stage III; tumor limited to the true pelvis but with histologically proven malignant extension to small bowel or omentum
IIIA	Tumor grossly limited to the true pelvis, with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces or histologically proven extension to small bowel or mesentery
IIIB	Tumor of one or both ovaries with histologically confirmed implants, peritoneal metastasis of abdominal peritoneal surface not exceeding 2 cm in diameter; nodes are negative
IIIC	Peritoneal metastasis beyond the pelvis >2 cm in diameter and/or positive retroperitoneal or inguinal nodes
IV	Growth involving one or both ovaries with distant metastases; if pleural effusion is present, there must be positive cytology to allot a case to stage IV; parenchymal liver metastasis equals stage IV

From Heintz AP, Odicino F, Maisonneuve P, et al: Carcinoma of the ovary: FIGO 6th Annual Report on the Results of Treatment in Gynecological Cancer. Int J Gynaecol Obstet *95(Suppl 1):S161–S192, 2006.*

[*] International Federation of Gynecology and Obstetrics (FIGO) nomenclature, Rio de Janeiro, 1988.

[†] To evaluate the impact on prognosis of the different criteria for allotting cases to stage IC or IIC, it would be of value to know if rupture of the capsule was spontaneous or caused by the surgeon and if the source of malignant cells detected was peritoneal washings or ascites.

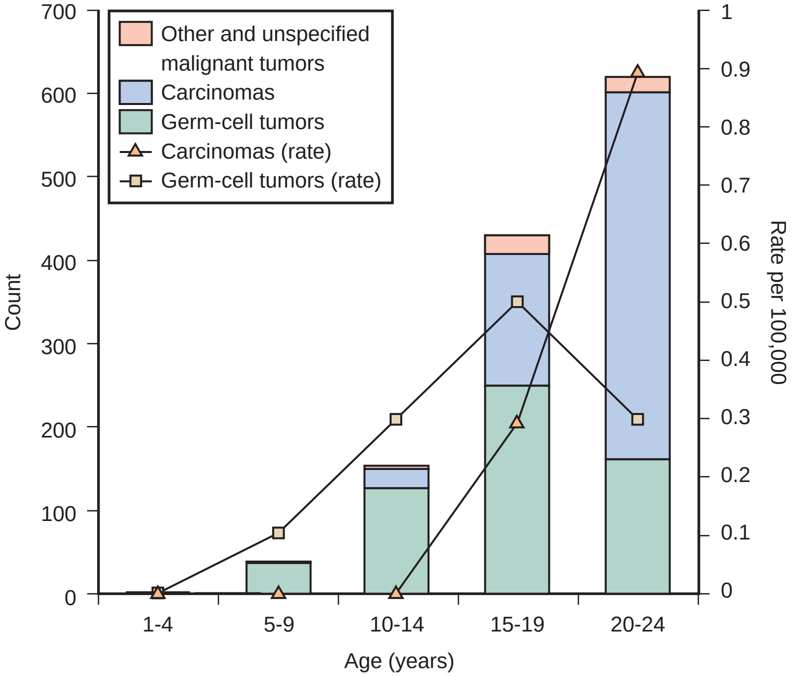

Figure 65-12 Incidence and rate per 100,000 cases of ovarian cancer in children and young adults, SEER-17 1998-2002.

most common ovarian tumor in adults, account for 15% to 20% of pediatric ovarian tumors, with most occurring after menarche when the rate increases markedly (Fig. 65-12). Unlike in adults, most pediatric epithelial ovarian tumors are localized, and pathologically most are of low malignant potential (borderline) or well differentiated.[224,227] Stage I tumors of potential low malignancy are appropriately treated by unilateral salpingo-oophorectomy alone, and have almost a 100% survival rate.[227] Surgery should include careful inspection of the peritoneum and contralateral ovary and lymph nodes.[228] For those rare children with invasive or advanced disease, platinum-based therapy developed for adult epithelial carcinomas has proven effective. Although a thorough family history should be obtained as a matter of course, studies suggest that breast cancer genes 1 and 2 (*BRCA1/2*), breast and ovarian cancer syndrome, and HNPCC syndrome account for few cases of epithelial cancer in women younger than age 30 years.[229-231]

Stromal Carcinomas

Tumors of the mesenchymal tissue of the ovary account for 15% of ovarian malignancies in pediatrics. Most present at an early stage and have a prognosis for survival higher than 85%.[232] Sertoli-Leydig tumors often cause overproduction of androgen precursors, producing virilizing symptoms of amenorrhea, masculinization, and hirsutism. Juvenile granulosa-cell tumors can overproduce estrogen and progesterone and present with precocious puberty. These tumors are sometimes classified with benign tumors, and many act in a benign fashion but have malignant potential and have been reported to metastasize and be fatal.[233] Nonlocalized tumors should be treated with adjuvant platinum-based chemotherapy with or without radiation.[234]

TUMORS OF THE CERVIX AND VAGINA

The most common nonovarian tumor of the female genital tract is rhabdomyosarcoma (82% in a registry series over 25 years in Great Britain), and the appearance of a protruding cluster-of-grapes vaginal mass in a young child is classic for sarcoma botryoides.[235,236] Cervical and vaginal carcinomas in children can be adenocarcinomas or squamous carcinomas; the ratio is skewed more toward adenocarcinoma in children than in adults. There is no known difference in causative factors, treatment, or prognosis between the two pathologies. Mesonephric adenocarcinoma is rare in adults but is a relatively more common subtype in children; it is thought to arise from mesonephric duct remnants and tends to arise deeply without reaching the endocervical surface.[237]

Cervicovaginal clear-cell adenocarcinomas are not associated with HPV infection. Rather, a peak of incidence in children and adolescent girls was a historic phenomenon caused by the maternal use of diethylstilbestrol (DES) therapy in pregnancy. Since its proscription, the tumor is again relatively uncommon in pediatrics. However, rates of non-DES cervical cancer in adolescents have been rising because of increasingly early sexual activity and higher rates of HPV infection.[238] HPV types 16 and 18 are the causative agents in more than 70% of cervical cancer. Around puberty the cervix has a particular biologic vulnerability to HPV infection, so that the sexually active adolescent has one of the highest risks of infection after exposure,[239] creating a risk for the development of squamous intraepithelial lesions that can progress over 10 to 15 years to invasive cervical cancer.[240] Recent data have shown that 27.8% of ninth-grade and 63.6% of twelfth-grade girls report having had sexual intercourse.[241] These sexually active female adolescents have high rates of genital HPV infection (13% to 64%) and abnormal Papanicolaou (Pap) smear results (as high as 38%).[239,240,242] The recent formulation of a vaccine against multiple strains of HPV is recommended for administration to 12-year-old girls—before anticipated initiation of sexual activity.[243] However, a 2010 survey found that only 32% of adolescent females ages 13 to 17 years complete the 3-dose series. In order to improve herd immunity and cost-effectiveness, the quadrivalent HPV vaccine is now recommended for adolescent males as well.[15-16] The natural history of progression of cervical abnormalities (from squamous intraepithelial lesions to cervical intraepithelial neoplasia) appears similar in adolescents and adults.[244] Recommendations for adolescents with abnormal Pap smears are available on the American Society for Colposcopy and Cervical Pathology website.

The most common clinical presentation of a cervical or vaginal tumor is vaginal bleeding, which may be difficult to distinguish from irregular menses in prepubescent and early pubescent girls. In one series evaluating causes of vaginal bleeding in children, tumors accounted for 11%.[245] These tumors often present at later stages in children and adolescents than adults because of the lack of screening Pap smears and hesitancy to perform pelvic examinations.[246]

Treatment includes surgical resection with lymph-node exploration and adjuvant radiation for residual disease or lymph nodes. This preference of surgery over radiation differs from therapy for adults because of the need to avoid radiation toxicity in younger, growing children. Novel uterus-sparing techniques (e.g., radical abdominal/vaginal trachelectomy) first adopted in adults to preserve fertility have been used successfully in children.[247,248] In a retrospective study of women younger than 25 years, localized cervical cancer had a 5-year survival rate of 91% and regional disease had a 5-year survival rate of 46%.[249] A series of 37 pediatric cases of vaginal and cervical adenocarcinoma from St. Jude Children's Research Hospital has found a 71% 3-year survival rate.[246] Other rare tumors reported in the cervix and vagina are alveolar soft parts sarcoma,[250,251] germ-cell tumors such as endodermal sinus (yolk sac) tumor and embryonal carcinoma,[236,252] and Wilms tumor.[253] These tumors are covered elsewhere in this text.

GESTATIONAL TROPHOBLASTIC TUMOR

Sexually active adolescents are at risk for these rare tumors, which arise as tumors of the products of conception. A hydatidiform mole, or molar pregnancy, is a uterine mass consisting only of placental-like tissue without an intact fetus. Pregnancies in those younger than 15 years have a sixfold risk of being molar.[254] Hydatidiform moles are treated by dilation and curettage with careful follow-up monitoring for resolution of elevated β-hCG levels.[255] Persistent or increasing β-hCG levels after a molar pregnancy, abortion, or term pregnancy indicate a malignant gestational trophoblastic tumor (GTT), the most aggressive of which is choriocarcinoma, a malignant tumor of the trophoblastic epithelium. The most common symptom is abnormal vaginal bleeding, but patients can also have asymptomatic pulmonary metastases or neurologic symptoms caused by brain metastases.[256] Patients with nonmetastatic or good-prognosis metastatic GTT are treated with single-agent chemotherapy (methotrexate, dactinomycin, or etoposide), and have an excellent prognosis.[257,258] Those with single-agent resistant or high-risk metastatic disease (high β-hCG, delay in start of chemotherapy, brain metastases, multiple sites of metastases) require multiagent cytotoxic chemotherapy.[259-261] The use of platinum and etoposide-based regimens has significantly improved salvage rates for high risk patients who fail initial multiagent chemotherapy.[262]

MELANOMA

Epidemiology

Pediatric melanoma, which has been classified as an epithelial malignancy by the International Classification of Childhood Cancer (ICCC), accounts for 30% of epithelial cancers in children and adolescents.[41,55] Although rare, particularly among prepubertal patients, it is estimated that nearly 450 cases of pediatric melanoma are diagnosed each year in the United States in patients younger than age 20 years[31] and most cases affect 15- to 19-year-old adolescents, in whom this malignancy accounts for 7.1% of all cancers (Fig. 65-13).[41]

The incidence of melanoma in children younger than age 20 years increased by 2.9% per year from 1973 to 2001, with the highest rates of increase in adolescents.[263] Most melanomas in pediatric patients affect white females, and over 80% are localized. The female-to-male ratio increases with age, especially during adolescence, and there is a preponderance of nonwhite patients, nodular histology, and head and neck sites in patients younger than 10 years of age.[263]

Risk Factors

Melanoma can be transmitted transplacentally, but this is a very rare phenomenon that is associated with a dismal clinical outcome.[264] Other risk factors associated with the risk of melanoma in the pediatric population include the presence of a large congenital nevus, retinoblastoma, Werner syndrome, prior history of childhood cancer, xeroderma pigmentosum, neurocutaneous melanosis, immunosuppression, familial melanoma, and dysplastic nevi.[265-267]

Clinical Molecular and Pathologic Features

Pediatric melanoma resembles adult melanoma in its clinical presentation and can arise in a preexisting nevus or de novo. The classic ABCDEs of melanoma (asymmetry, border irregularity, color variegation, diameter larger than 6 mm, and an evolving lesion) are commonly reported in childhood and adolescent cases, but the presence of other lesions such as Spitz nevus or amelanotic lesions may make diagnosis difficult and delay the diagnosis. It is estimated that up to 60% of pediatric patients with melanomas are initially misdiagnosed.[266,268] The pathologic diagnosis of melanoma may be often difficult and challenging. Increasing evidence has suggested that

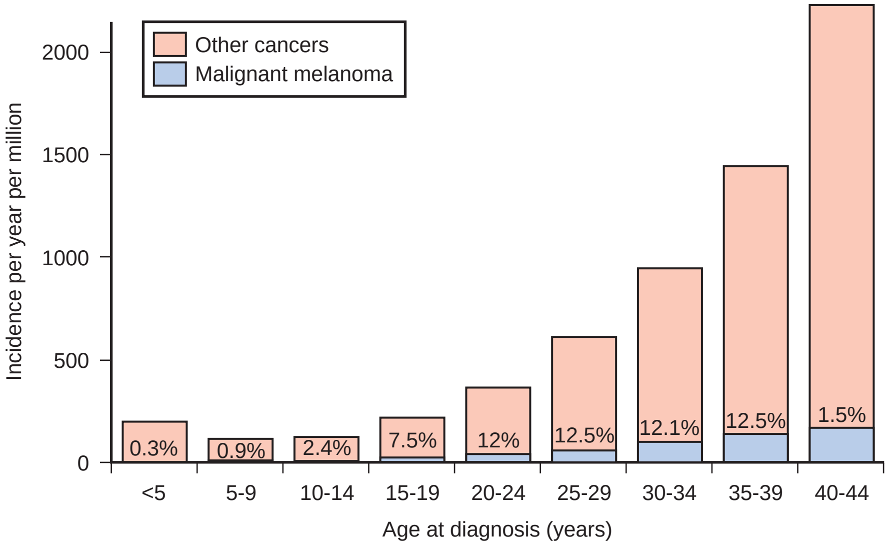

Figure 65-13 Incidence of malignant melanoma relative to all cancer, SEER 1975-2000.

pediatric melanoma may have a significant variability in its pathologic spectrum. The term *melanocytic lesion with unknown metastatic potential* has gained popularity in recent years, adding to the uncertainty and confusion of diagnosing pediatric melanoma.[269] The use of fluorescence in situ hybridization (FISH) probes sets that target 6 distinct chromosomal loci has identified 9p21 deletions and 6p25, 11q23 gains as markers of aggressive behavior.[270] About 50% of pediatric melanomas have a *BRAF V600* mutation that can be targeted with available therapies for adults.[271,272]

Diagnosis and Staging

Since there is no validated system for children, guidelines for diagnosing and staging children with melanoma have been extrapolated from adult studies. Adhering to the current AJCC guidelines for staging all pediatric patients with melanoma is recommended.[273] The use of routine imaging in children with melanoma has not been studied prospectively, but in one study 25% of patients with thicker lesions had evidence of distant disease on CT of the chest and abdomen. The routine use of PET imaging for staging pediatric melanoma has not been studied prospectively, but in adults it has not revealed a significant patient-relevant benefit.[274] Early detection and biopsy are imperative, and when melanoma is suspected the pathology report should include the type of melanoma, depth, mitotic count, and surgical margins. Nodal staging using sentinel node biopsy has become commonplace in pediatrics and should be performed in children with lesions greater than1 mm thick and may be considered in children with thinner lesions if they display one or more high risk features such as Clarks level of invasion IV or V, ulceration, and high mitotic rate ($>0/\text{mm}^2$).[275]

Treatment and Outcome

Surgery is the treatment of choice for pediatric melanoma. For patients with lesions greater than 1 mm a wide excision with a 1-cm margin is appropriate. For those that are 1 to 2 mm, a 1- to 2-cm margin is recommended, and for those thicker than 2 mm a 2-cm margin should be used.[276] After a positive sentinel node it is recommended that a patient be offered a complete lymph node dissection, because about 16% of these patients have occult nodal metastases; however, a survival advantage after this procedure has not been clearly demonstrated.[277,278] The administration of adjuvant high-dose interferon improves relapse-free survival in adult patients with high-risk melanoma, and this option should be offered to patients at high risk for recurrence.[279] Although single-institution studies suggest that high-dose interferon is well tolerated in children with melanoma, its use has not been studied prospectively in large numbers of patients.[280-282] Subcutaneous pegylated interferon for up to 5 years has been shown to prolong disease-free survival in adults with resected microscopic nodal disease and ulceration.[283] Its use in pediatrics has been limited, and results of clinical trials using this agent in children have not been yet published. Because *BRAF V600* mutations are seen in up to 50% of pediatric melanomas, the use of targeted therapies such as vemurafenib and dabrafenib should be explored further. There is a pediatric trial using vemurafenib for patients 12 to 17 years of age with measurable *BRAF V600* mutated melanoma. Ipilimumab, a monoclonal antibody directed against the inhibitory molecule cytotoxic T-lymphocyte antigen 4 (CTLA4), has improved survival in adults with metastatic melanoma, and a pediatric trial is being conducted.[284] In addition, other novel immunotherapies such as BMS-936558, a monoclonal antibody directed against programmed death receptor 1 (PD1), and BMS-936559, a monoclonal antibody directed against programmed cell death 1 ligand 1 (PDL1), has produced encouraging responses in adults with metastatic melanoma, but a pediatric trial is not available.[285,286] The overall survival of pediatric melanoma is stage-dependent and overall excellent, with

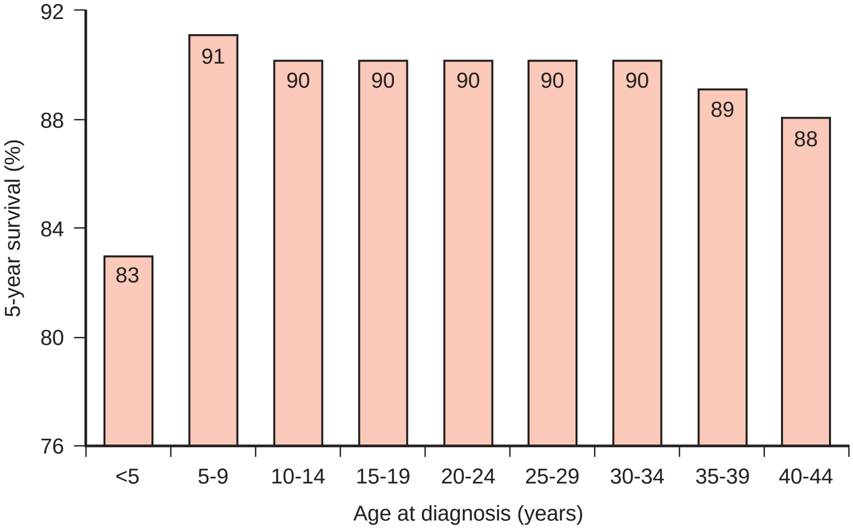

Figure 65-14 5-year survival rate for melanoma, SEER 1975-1999.

5-year survival rates in excess of 90% except in those who are younger than 10 years of age (Fig. 65-14).

SURVEILLANCE IMAGING
CONCLUSION

The incidence of cancer in childhood is relatively rare when compared to the incidence in adults; approximately 6500 new cases are diagnosed in the United States each year. Nevertheless, cancer remains the second most common cause of death during childhood. Beginning in the mid-1960s treatment of childhood cancer has witnessed remarkable advances in chemotherapy, radiotherapy, and surgical intervention, with improvements in survival for the majority of pediatric malignancies. The imaging of children with malignancy has also evolved, with significant technical advances in both diagnostic and interventional radiology techniques. Faster magnetic resonance (MR) and computed tomography (CT) scanners, three-dimensional (3D) acquisition and postprocessing techniques, and an increasing number of hybrid imaging technologies allow practitioners to image children more quickly, accurately, and safely, in addition to providing options for image-guided diagnostic and therapeutic procedures that historically required surgical intervention. This chapter provides an introductory overview of the various diagnostic imaging techniques available and a review of the imaging findings commonly seen in a broad spectrum of pediatric tumors. The chapter concludes with a discussion of diagnostic and therapeutic interventional

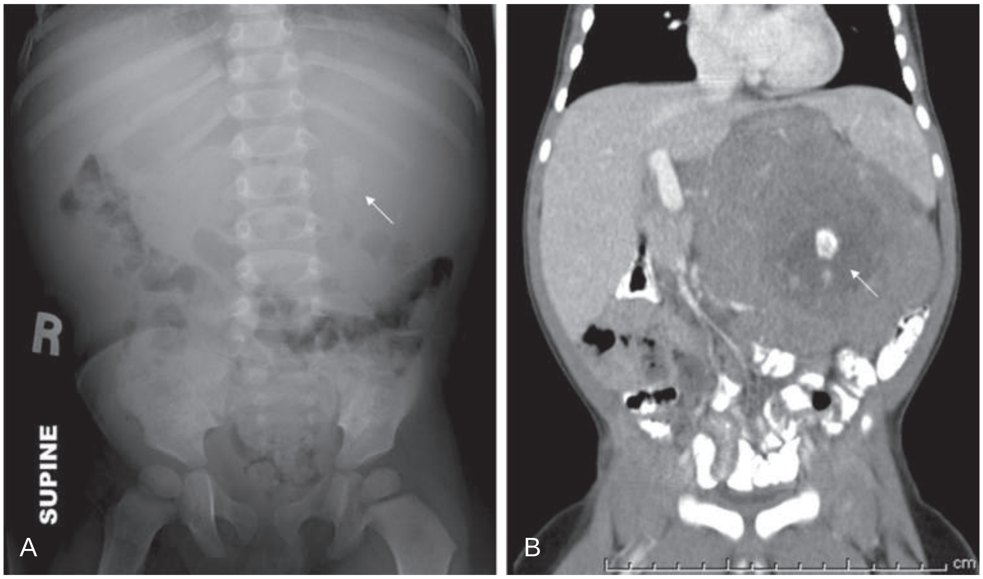

Figure 66-1 Neuroblastoma, detected incidentally. A 20-month-old infant fell, and caregivers felt a firm abdomen with no other symptoms. Abdominal radiograph (**A**) shows a calcified abdominal mass *(arrow)*, further characterized by CT (**B**) and found to be neuroblastoma.

radiologic techniques, surveillance imaging considerations, and finally a brief introduction to the evolving field of molecular imaging and novel imaging technologies.

TECHNICAL CONSIDERATIONS

Conventional Radiography

The decision to perform an imaging study on a child and the type of imaging that is selected very much depend on the patient's clinical history and physical examination findings. In young children with cancer, initial presenting symptoms and complaints are often nonspecific. An easily performed, relatively inexpensive imaging assessment like an x-ray is therefore appropriate as a first step in the evaluation. Conventional radiography is still commonly used as the first imaging examination undertaken both in children with suspected malignancy and in patients with nonspecific complaints that ultimately turn out to be related to neoplastic disease. These initial imaging studies provide valuable initial information that can help suggest a differential diagnosis and inform decision makers about subsequent imaging evaluations.

Although it is tempting to forego obtaining conventional radiographs in favor of cross-sectional imaging modalities such as ultrasound and CT, it is still appropriate in most instances to obtain conventional radiographs as a first step. Normal x-rays in certain settings may provide needed reassurance. Abnormal radiographs, on the other hand, provide a sensitive and accurate initial means of identifying pathology. For example, abdominal films allow assessment for bowel obstruction or perforation and may show solid mass lesions, abdominal calcifications, or areas of bone destruction (Fig. 66-1). Chest radiographs often reveal primary intrathoracic or mediastinal tumors and pulmonary metastases. Chest radiographs are also critical in suggesting impending airway compromise, pneumothorax, or pneumomediastinum and are rapidly obtained, easy to perform, and fairly quickly interpreted. Oncologic emergencies are fortunately uncommon; however, cardiorespiratory emergencies in a child, such as pneumothorax or pneumomediastinum, airway compression secondary to a large mediastinal mass (Fig. 66-2), and malignant pericardial or pleural effusions can be effectively evaluated in the emergent setting by properly executed chest and abdominal radiographs. Indeed, a CT scan may be contraindicated if radiographs indicate the presence of significant airway compromise in the setting of a large mediastinal mass, because supine positioning with or without sedation may lead to further airway compression, impaired venous return, and acute cardiorespiratory collapse.[1]

Radiographs are essential for initial imaging of nonspecific orthopedic complaints such as pain and limp and may lead to the diagnosis of marrow infiltrative disorders such as leukemia and neuroblastoma (Fig. 66-3, *A*). Radiographs are also necessary for evaluation of primary bone tumors such as Ewing sarcoma and osteogenic sarcoma, where the presence of calcifications, periosteal reaction, bone destruction, and soft-tissue involvement are important in formulating an initial impression and plan. Conventional radiography also plays a role in specific conditions such as Langerhans cell histiocytosis, where skeletal surveys are still used to detect the lytic lesions characteristic of this disease (see Fig. 66-3, *B*). Whether whole body MRI or 18-fluorodeoxyglucose positron emission tomography (FDG-PET) scanning can be used to improve the sensitively and specificity of detecting these lesions has been the subject of several investigations.[2-5]

The role of fluoroscopy in the primary evaluation of pediatric oncology patients is limited and has been largely replaced by CT. CT provides the advantage of visualizing both endoluminal and surrounding mesenteric/intraperitoneal/retroperitoneal processes, for which traditional fluoroscopic evaluations are limited.

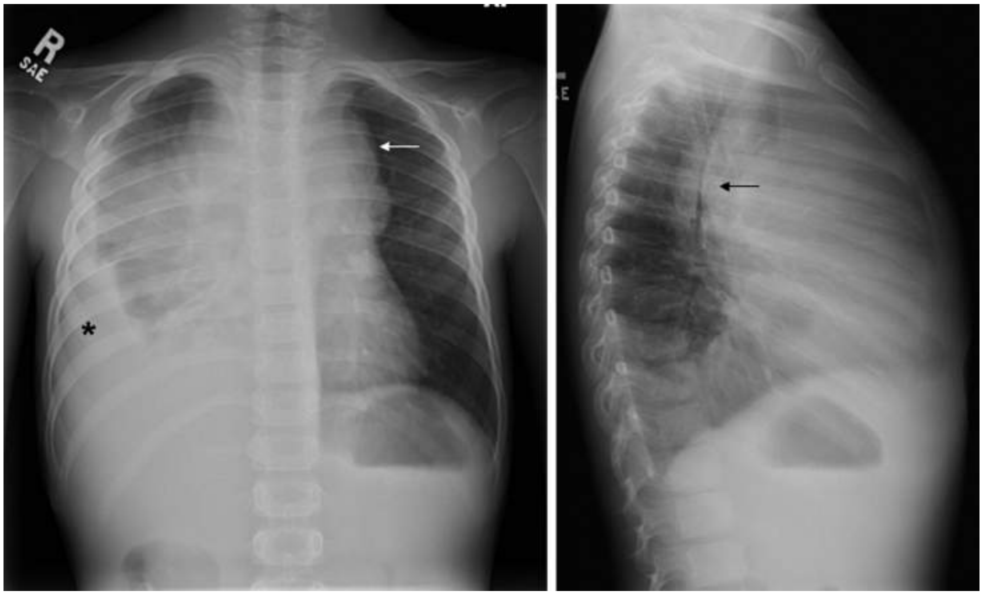

Figure 66-2 Incidentally discovered lymphoma. A 5-year-old boy, otherwise well, developed fever and cough and was treated for pneumonia. The chest x-ray, obtained for persistent symptoms, showed a large mediastinal mass *(white arrow)*. Note large pleural effusion *(asterisk)* and marked tracheal narrowing *(black arrow),* placing this child at considerable risk for acute cardiorespiratory compromise. The biopsy showed T-cell lymphoblastic lymphoma.

Ultrasound

The use of ultrasound in pediatric radiology is ubiquitous. Ultrasonography is relatively inexpensive, can be done portably, involves no radiation, and in skilled hands can be used to accurately assess an anxious, moving child for whom sedation may pose additional risk. Technically ultrasound relies on the use of variable penetration and attenuation of sound waves by different tissue types. The routine ultrasound examination typically involves the combination of B-mode (brightness mode) scanning and either color or pulsed wave/duplex Doppler sonography to assess flow within vascular structures. As an initial screening modality, ultrasound is very sensitive at evaluating intraabdominal solid organ viscera and is the initial imaging modality of choice in the evaluation of Wilms tumor, neuroblastoma, and hepatoblastoma. Pelvic neoplasms, intraperitoneal free fluid, and musculoskeletal soft-tissue tumors can all be effectively evaluated by ultrasound.

Newer ultrasound imaging techniques rely on a large array of transducers, which afford high-resolution images independent of the size of the patient and depth of the lesion. Extended field-of-view image-processing algorithms offer the capability of visualizing large masses in their entirety along with their relationships to normal structures. Although not in routine clinical use, 3D ultrasound allows images to be displayed in multiple planes and may be useful in demonstrating relationships between solid-organ malignancies and adjacent normal structures.[6] Ultrasound contrast agents are in common use experimentally and have the potential to add to the diagnostic information obtained by conventional ultrasound, but they are not yet being used routinely in clinical practice.[7-9]

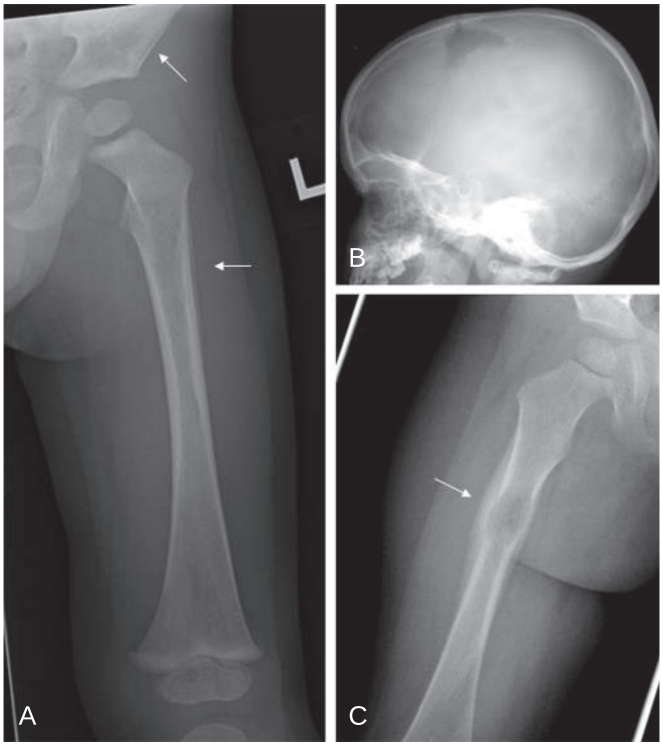

Figure 66-3 Two children with limp. **A**, 23-month-old child; hip and femur radiographs showed periosteal reaction involving femur and supraacetabular ilium *(arrows)*. The ultrasound revealed an abdominal mass, which on biopsy was neuroblastoma. **B** and **C**, 25 month-old-child with lytic skull lesion (**B**) that was revealed on a skeletal survey, which was obtained after extremity radiographs taken for limp identified a lytic femoral lesion with periosteal reaction (**C**). Biopsy showed Langerhans cell histiocytosis.

Ultrasound is also used intraoperatively to help identify lesions that are not visible, not palpable, or undetectable using other imaging techniques. Intraoperative ultrasound can also play an essential role in helping the surgeon identify a plane between tumor and adjacent normal tissue, which can be vital when tissue-sparing surgical techniques are desirable, such as nephron-sparing partial nephrectomy (see "Renal Masses") and partial hepatectomy.[10]

Computed Tomography

After ultrasound, CT scanning remains the primary imaging modality for evaluating most pediatric solid tumors. It is readily available in the majority of institutions, can be performed rapidly (often without sedation), and with newer generation scanners provides high spatial resolution and multiplanar viewing capabilities. CT scanning involves the use of a fan-shaped or cone-shaped x-ray beam generated by the x-ray tube rotating 360 degrees around the body part being examined. At the same time the x-ray tube rotation is occurring, the patient is moving longitudinally through the scanner, allowing the sequential and nearly simultaneous examination of multiple contiguous body parts. Once the x-rays pass through the patient, they strike an array of photodetectors that convert the x-ray energy into electrical signals, which are then used to reconstruct images from the region of the body through which the x-ray beam penetrated. The current generation of scanners are called *multidetector-row helical CT scanners* and rely on multiple detector rows (up to 256) to simultaneously acquire imaging information from larger segments of tissue.[11,12] This allows for more rapid scanning and also allows the reconstruction of imaging data in multiple planes with minimal artifact and image distortion. These multiplanar reconstructions also allow volumetric data to be evaluated, which may be important in assessing response to therapy.[13-14,15,16] In addition, the ability to view images in multiple planes with two-dimensional (2D) and 3D reconstructions and the ability to export images to robotic-assisted surgical devices is increasingly used by surgeons for both preoperative planning and intraoperative guidance in complicated cases.

For infants and anxious young children, it may be necessary for patients to be sedated in order to acquire high-quality imaging. In the majority of patients, sedation can be performed safely and effectively with skilled nursing staff and monitoring equipment.[17,18] In particular, sedation is usually necessary before infusion of intravenous contrast agents, because the contrast infusion may be startling to an otherwise calm child, and motion artifact severely compromises the image quality.

The use of intravenous contrast agents, particularly for the majority of pediatric solid tumors, is necessary to properly show relationships between primary neoplasms and adjacent structures. Although centers less experienced in the care of pediatric patients may consider performing scans without the use of intravenous contrast based on perceived increased risks of contrast reactions in children, a retrospective review of CT scanning results from over 12,000 contrast-enhanced studies performed over 5 years showed less than 0.5% incidence of contrast reactions (57 reported adverse events), with the vast majority being minor reactions. No severe contrast reactions occurred in infants or very young children.[19] Based on this and the results from other pediatric centers[20] there is little data to support the routine omission of intravenous contrast in the evaluation of children suspected of having malignancy. In particular, the use of nonionic low osmolar agents can be performed very safely in the majority of patients and are the contrast agents of choice in most large pediatric radiology departments. Enteric contrast is also recommended to opacify the bowel lumen, allowing better discrimination between normal viscera and potential sites of mesenteric or retroperitoneal lymph-node enlargement. Historically barium had been used, but this has been largely replaced by low-osmolar water-soluble contrast agents that can be mixed with water or juice, produce fewer streak artifacts, and do not affect other imaging studies such as PET and single-photon emission CT (SPECT) imaging.

Optimal imaging of the thorax for the purpose of evaluating the mediastinum and hilar structures requires the use intravenous contrast, whereas CT scanning of the chest to assess for pulmonary metastatic disease can generally be performed without the use of intravenous contrast. The use of multiplanar reconstructions and the ability to review slices in very thin sections improves detection of pulmonary nodules,[21,22] although the ability to discriminate benign from malignant pulmonary nodules based on CT is still limited.[23] In infants and small children who are either asleep or in whom quiet breathing can be encouraged, the speed with which current generation scanners can acquire images may allow noncontrast examinations of the chest to be performed without sedation. In older children for whom breath-holding is possible, image quality and sensitivity/specificity of pulmonary nodule detection is improved when images are obtained at the end of inspiration. If breath-holding is required for a child requiring sedation, anesthesia consultation should be obtained to determine the need for general anesthesia and endotracheal intubation versus using positive pressure laryngeal mask ventilation.[24]

The use of intravenous contrast agents also requires skill on the part of the radiologist in interpreting the examination, with awareness of potential causes of artifact. In particular, the spleen has a variable pattern of enhancement that is well appreciated but can be confused for splenic disease, particularly in the setting of lymphoma. Delayed scanning can usually help in discriminating artifact from disease.[25] In addition, acquisition of images at multiple phases after contrast infusion is often helpful in detecting subtle foci of disease that may only be seen at early arterial phases of enhancement, particularly in the liver (Fig. 66-4). Other lesions, in contrast, may only become evident after delayed enhancement, and knowledge of the typical patterns of enhancement for the particular disease that is being evaluated or suspected is important in determining the scanning technique.[26] It is still common to perform evaluations for hepatoblastoma in both hepatic arterial and portal venous phases in order to maximize sensitivity of lesion

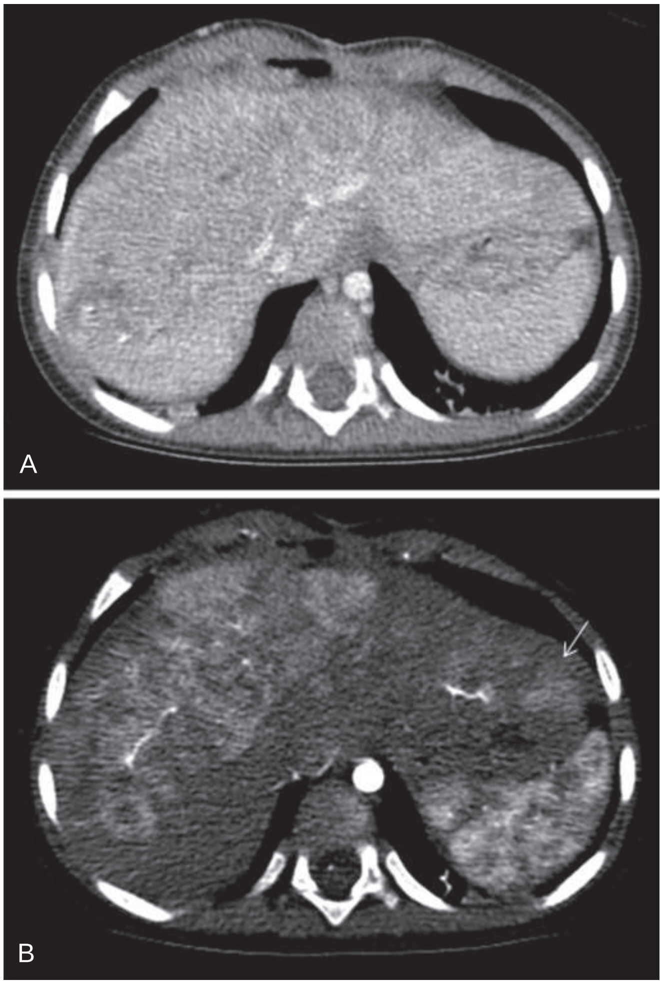

Figure 66-4 A 20-month-old child with unresectable hepatoblastoma, emphasizing the importance of multiphase scanning for optimal lesion detection. The presence of the left lateral segment lesion *(arrow)* was only seen on early arterial-phase scanning. Its identification determined surgical unresectability in this patient.

detection, delineate vascular anatomy, and provide optimal images to aid in surgical planning, although in many centers, improvements in abdominal MR image quality together with concerns about radiation related to repeated CT scanning have resulted in increasing use of MR imaging (MRI).[27]

Discussions of radiation dose in the setting of diagnostic CT scanning have become widespread in both the imaging and wider medical literature.[28-33] The data indicate measurable increases in incidence of malignancy attributable to radiation doses during diagnostic CT scanning, with cumulative increases in risk with increasing numbers of scans. Although these concerns are not to be underemphasized, particularly for otherwise well patients undergoing screening examinations, for patients with known malignancy or in whom malignancy is suspected, the relative benefit derived from the high-quality information achieved after diagnostic CT scanning almost always outweighs the modest incremental increase in risk associated with these techniques.[34] Nonetheless every effort should be made to limit the examination to involved regions of the body and to minimize the frequency of scanning in these heavily evaluated patients, using the "as low as reasonably achievable" (ALARA) principle as guidance.[31,32,35-37]

Magnetic Resonance Imaging

The physical principles of MR image formation are beyond the scope of this chapter and can be reviewed in articles devoted to this subject.[38,39] MRI involves the use of an external magnetic field to orient protons (primarily contained in water molecules) within the body, after which radiofrequency pulses are applied with specific frequencies and orientations. These radiofrequency pulses force the protons aligned in the magnetic field to come out of alignment. After the radiofrequency energy is withdrawn, the protons gradually reassume their original alignment, or resonate, within the magnetic field. The process of relaxation is multidimensional, and the rate with which longitudinal and transverse relaxation (T1 and T2 relaxation times, respectively) occurs is dependent on the properties of the specific tissue. The energy released during this realignment process can be measured much in same way that a standard radio receiver acquires the signal (radiofrequency energy) from a radio station transmitter. This radiofrequency energy can be characterized both in terms of its spatial location and frequency, and this information in turn can be used to reconstruct images. The result is high resolution MR images obtained in multiple orientations and tissue planes with signal properties that reflect the tissue microenvironments within which the protons reside.

High field-strength and low field-strength magnets are in common clinical use. In general terms, with higher field strength there is a higher signal-to-noise ratio.[38,40] Despite this, the high field-strength magnets are susceptible to some image degradation and magnetic field artifact, and most imaging can be reliably performed at 1.5 and 3 Tesla. With lower field strengths, the signal-to-noise ratio is considerably diminished. There are a variety of radiofrequency coils that are utilized as receivers for the radiofrequency energy emitted during proton relaxation and reorientation. Newer coil designs allow for rapid scanning techniques and for high-resolution imaging of specific body parts to be performed.[38,41]

Multiple MR images of the same organ or tissue are typically generated; however, the imaging technique chosen results in different patterns of tissue contrast, allowing the unique features that characterize distinct components of an organ or tissue to be depicted. The tissue contrast that one observes is the result of the interplay between the externally applied magnetic field, the inherent properties of the tissue (i.e., freely mobile water protons or highly ordered soft-tissue protons), and the radiofrequency pulse-sequence parameters chosen to acquire the image. The tissue properties that have the greatest influence on image contrast are the proton density (PD) and the T1 and T2 proton relaxation times. Conventional MRI techniques are acquired with "T1- and T2- weighting," in which the tissue contrast is weighted to reflect differences in the T1 and T2 relaxation times among the different tissues. This is accomplished by varying the interval between which the radiofrequency pulses are applied (the pulse repetition time, or TR) and the time that is allowed before the emitted signal is received (the echo time, or TE). T1-weighted images typically have a short TR (300 to 600 msec) and short TE (10 to 20 msec) and emphasize T1 characteristics of tissues. On T1-weighted images, fat is typically bright, fluid has low signal intensity, and complex or proteinaceous fluid is of intermediate to high signal intensity. Conventional contrast agents used in MRI result in T1 shortening and therefore produce increased signal on T1-weighted images.

T2-weighted images have longer TR (greater than 2000 msec) and longer TE (greater than 80 msec). T2-weighted images obtained using standard techniques display simple fluid such as cerebrospinal fluid (CSF) or urine as bright in signal intensity, whereas fat is low in signal intensity. Muscle and solid organs, depending on their tissue make-up, have variable signal intensity on T2-weighted images. Beyond these simple T1- and T2-weighted images, specific pulses sequences can be created that eliminate fluid signal (fluid-attenuated inversion recovery, FLAIR) or provide fat suppression either using chemically selective fat suppression techniques or so-called *inversion recovery techniques,* in which the TE is selected to minimize signal from fat and maximize signal from non–fat-containing structures.

Diffusion-weighted MR imaging (DWI) has also emerged as an important technique for evaluation of malignancy.[42,43] DWI is sensitive to the molecular motion of water within the imaging volume and historically was developed for neuroradiologic applications, where it became routine for evaluation of CNS ischemia, identifying early areas of potentially reversible cellular damage by virtue of restricted water diffusion across ischemic cellular membranes. Tumors also commonly demonstrate restricted diffusion relative to surrounding tissue because of increased cellularity and reduced extracellular space. With improvements in gradient echo imaging techniques, DWI can help identify subtle sites of disease (Fig. 66-5) and in some instances distinguish benign from malignant disease.[44] DWI changes in response to therapy, with increasing free diffusion of water molecules in areas of cellular necrosis as opposed to the more restricted movement of water in cellular regions of a tumor, has also been shown to correlate with tumor necrosis induced by treatment, and is emerging as an important technique in assessing response to therapy.[45,46,47,48]

MRI angiography and MR spectroscopy are all standard imaging techniques in common practice in the evaluation of the central nervous system (CNS). MR angiography takes advantage of rapidly flowing blood moving in and out of the imaging slice. Alternatively, gadolinium (Gd)-enhanced MR angiography relies on the use of Gd-based contrast agents to display the vasculature. The use of dynamic enhanced MRI allows multiple acquisitions in a specific region such as a tumor to be obtained, and there is evidence to suggest that the relative rates of contrast uptake and perfusion in tumors may be a reflection of tumor cellularity and/or necrosis.[49,50]

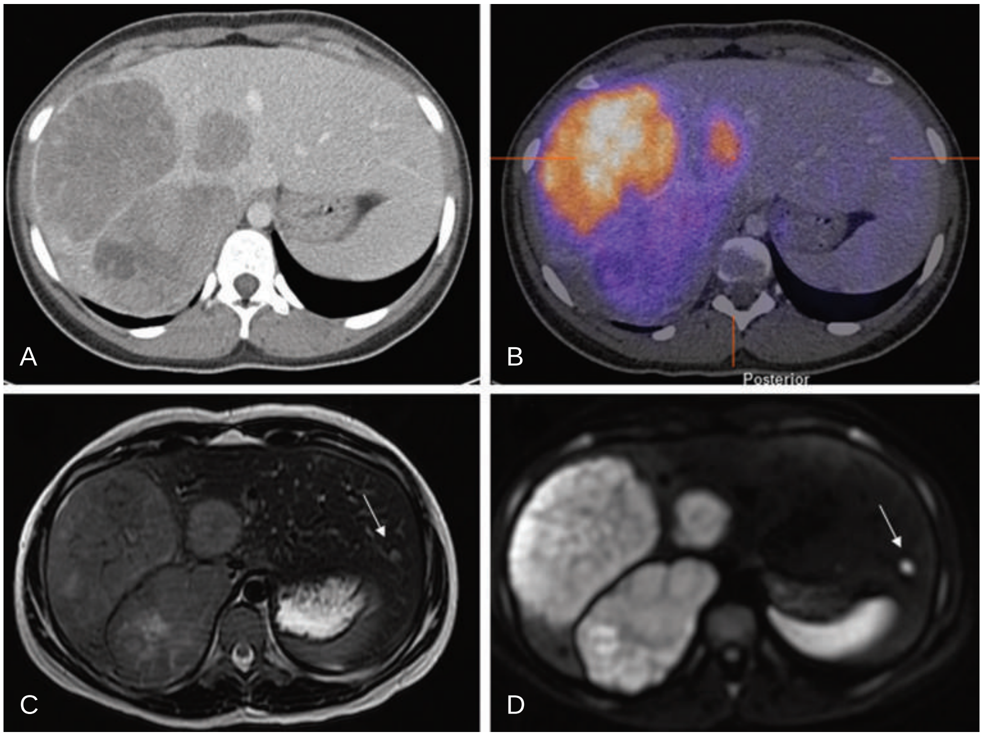

Figure 66-5 A 17-year-old adolescent with adrenocortical carcinoma primarily involving the right lobe. A small, metastatic deposit in the left lateral segment of the liver was not detectable by CT (**A**) or PET (**B**), is barely detectable on conventional T2-weighted MRI (**C**, *arrow*), but is easily seen on DWI (**D**, *arrow*).

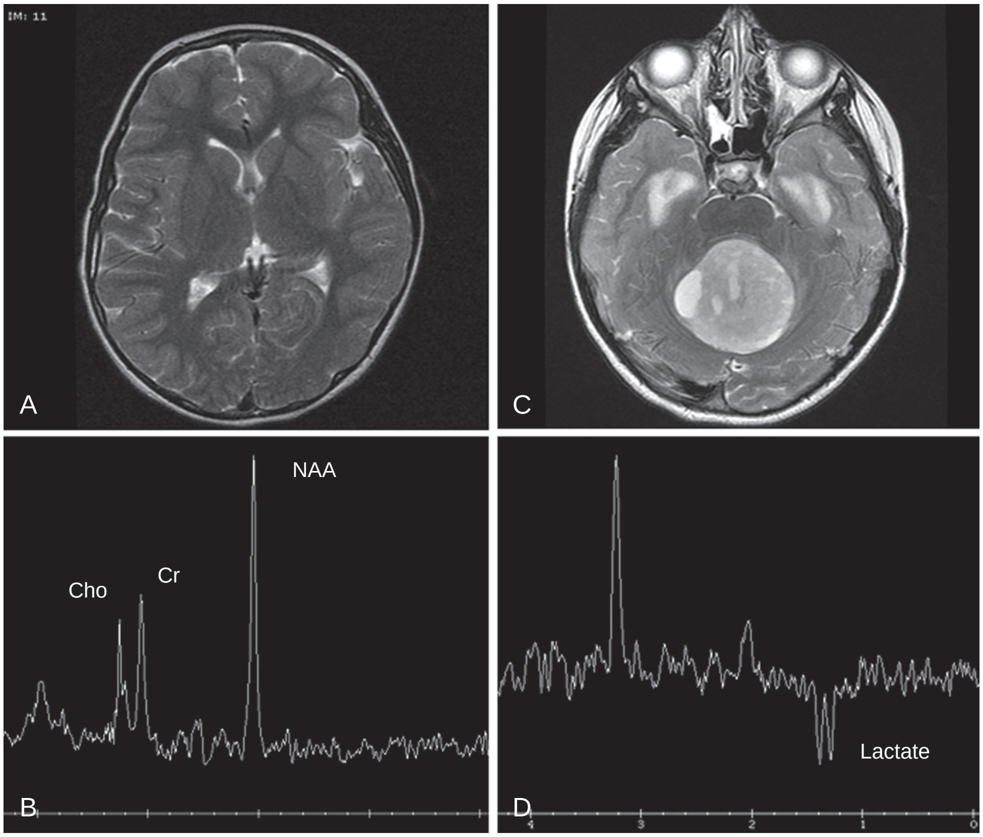

Figure 66-6 MRI and MR spectroscopy in a patient with medulloblastoma (**C** and **D**) compared with the normal MRI and spectrum on the left (**A** and **B**), demonstrating the increased Cho peak, decreased/absent NAA peak, and lactate peak characteristically seen in malignant lesions. *Cho,* Choline; *Cr,* creatine; *NAA,* N-acetylaspartate.

Contrast-enhanced angiography in particular may be useful as well for characterizing relationships of abdominal and mediastinal masses to critical adjacent vascular structures.

MR spectroscopy is used routinely in the evaluation of CNS tumors, where the metabolites N-acetylaspartate (NAA), creatine (Cr), and choline (Cho) have been defined and have specific and characteristic spectra. The use of spectroscopy, although not entirely diagnostic, adds additional information in evaluation of CNS tumors.[51,52] For example NAA is generally thought to correlate with neuronal density, whereas increases in Cho levels usually signify increases in cell density and membrane turnover, reflecting the relatively rapid metabolic rate and division of actively dividing tumors. NAA peaks are typically decreased or absent in pediatric brain tumors, and a decreased NAA/Cho ratio is a characteristic finding.[53,54] The presence of a prominent lactate peak, which is not usually present in the normal brain spectrum, signifies an increase in cellular hypoxia and necrosis (Fig. 66-6) and has been described in more malignant CNS neoplasms.[52] Because the obtainment of good spectral data relies on relatively static body parts, proton spectroscopy has not been used routinely outside the brain; however, investigations are underway to develop a better understanding of the spectra achieved in pediatric neoplasms outside the CNS.[55]

In addition to the use of spectroscopy and diffusion-weighted imaging for characterization of brain tumors, diffusion MR tractography based on diffusion tensor imaging (DTI) has rapidly become an important clinical tool that can delineate functionally important white matter tracts for surgical planning (Fig. 66-7). Tractography based on diffusion MR utilizes the correlation between water diffusion and brain structure to delineate the course of white matter pathways.[56] White matter tracts in the brain are highly organized into fasciculi comprised of densely packed axons. Axonal membranes, myelin, and other structures affect the pattern of Brownian motion of water within white matter. Tractography involves following the trajectory of the white matter tract from voxel to voxel in three dimensions by assuming that the direction of least restricted diffusion corresponds with the axon orientation.

While quantitative assessments of tissue microstructure are essential for many applications of diffusion MR, these measurements are not directly used for presurgical tractography.[57] Instead, the aim of presurgical tractography is to delineate the position of eloquent pathways such as the motor, sensory, visual, and language tracts. One of the goals of brain surgery is to avoid damage to eloquent cortex and subcortical white matter. DTI is the only noninvasive method available to segment the subcortical course of a white matter tract. Subcortical motor evoked

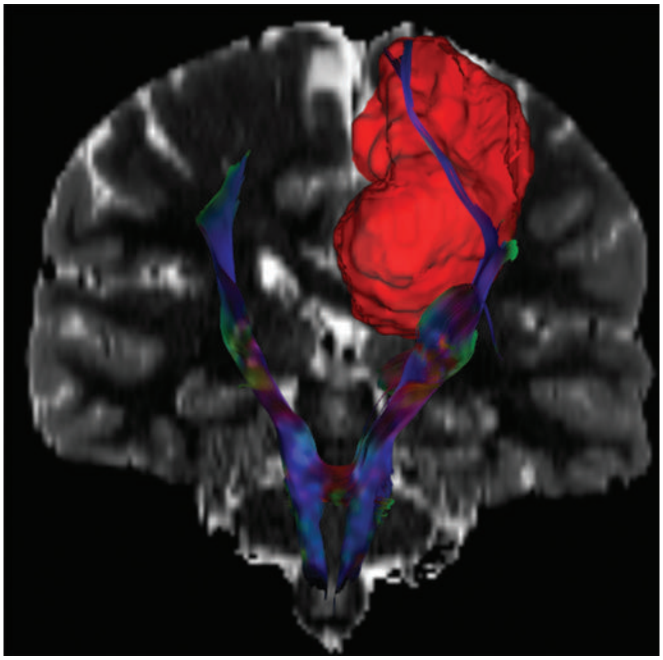

Figure 66-7 Diffusion MR tractography of the corticospinal tracts in a patient with a left-sided tumor showing displacement of the tracts by the tumor (*segmented and shown in red*).

potentials are often combined with tractography to preserve motor function.

Functional MRI (fMRI) using the blood oxygenation level–dependent (BOLD) method allows mapping out of the eloquent areas and is a noninvasive, repeatable, and flexible technique for studying brain function in the clinical setting (Fig. 66-8). It is often critical in surgical planning before resection of brain tumors and has become the standard of care for neurosurgical planning in centers where it is available. Although paradigms to measure eloquent cortices have not been standardized, simple tasks allow visualization of reliable maps for planning neurosurgical procedures. Current research indicates that patient-specific paradigm design can help refine the utility of fMRI for prognostication and recovery of function.[58] It should be noted that certain pathologic conditions and technical issues limit the interpretation of fMRI maps in clinical use and should be considered carefully.

Nuclear Medicine

PET has emerged as an important imaging tool in the evaluation of both adult and pediatric patients with malignancy. A number of textbooks and reviews have been dedicated to this topic and should be consulted for a more in depth discussion of this exciting technology.[59-68] The use of ^{18}F-fluorodeoxyglucose (^{18}F-FDG) has been routine in adult practice and is becoming increasingly commonplace in the evaluation of children with cancer.[69,70,72,128] FDG-PET scanning relies on the differential uptake of glucose by metabolically active tumor cells relative to surrounding tissues. The use of FDG-PET has been shown to be feasible in the majority of pediatric tumors[64,70] and is likely to play an important role in monitoring responses to therapy, particularly with agents that do not produce immediate tumor shrinkage or cellular necrosis but do block specific metabolic pathways. Although flourine-18 (^{18}F) is the most common PET radionuclide used clinically, other agents are being developed and are in preclinical testing, including copper-64 (^{64}Cu)[73,74] and iodine-124 (^{124}I)[75,76] and gallium-68 (^{68}Ga).[76] The use of biomarkers other than fluorodeoxyglucose is starting to emerge clinically, with compounds such as fluorinated thymidine (FLT) allowing deoxyribonucleic acid (DNA) synthesis and cellular proliferation to be directly imaged.[77]

Multiple studies have shown that the use of PET imaging alone, without the simultaneous review of anatomic imaging data acquired either by CT or MRI, results in high sensitivity of lesion detection but has an increased incidence of false positives and an overall decreased specificity. The use of correlative cross-sectional imaging improves the specificity of lesions detected by PET scanning and also increases the sensitivity with which lesions are detected by conventional imaging techniques.[78-80,81,82] As a result, integrated PET/CT scanners have rapidly replaced stand-alone PET imaging equipment in most centers, allowing the PET scan and CT scan to be obtained on the same instrument with the patient in the same position and orientation. This has revolutionized the use of PET scanning in evaluation of oncology patients, and in many institutions it is considered standard of care for PET scans and CT scans to be reviewed simultaneously by skilled radiologists and nuclear medicine physicians, who use the complementary information available from both imaging modalities to achieve greater confidence in rendering a diagnosis.[79,83] Current state-of-the

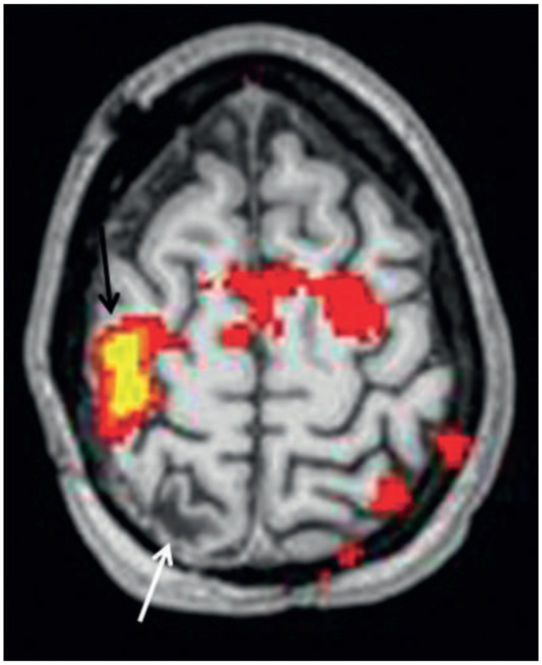

Figure 66-8 Functional MRI (fMRI) in an 18-year-old patient with a history of right posterior parietal oligoastrocytoma resection *(white arrow)*, now showing epilepsy localized to around the surgical cavity. fMRI activation using left-finger tapping shows robust, right-lateralized activation of the primary motor cortex *(black arrow)* and subtle activation of midline supplementary motor cortex.

art equipment utilizes high-sensitivity multirow PET detectors and multidetector-row CT scanners, allowing imaging to be performed more rapidly, with greater sensitivity, and, depending on the equipment, can incorporate respiratory and cardiac gating functions to improve image quality. Postprocessing techniques, relying on newer software, also allow the functional data from PET scanners to be fused to MRI images acquired separately, much in the same way that the PET images are fused to their correlative CT data.

In 2011 the first integrated PET/MRI scanners were approved by the FDA for clinical use and have now been installed at a number of major academic centers in the United States, Europe, and Asia. As with PET/CT, the PET/MRI scanners allow the PET scan and MRI scan to be simultaneously acquired.[84-86] The advantages include lower radiation exposure, the ability to integrate quantitative MRI data with concurrently acquired functional PET data, and the increasing use of MRI for characterization of many pediatric malignancies. As additional PET tracers become available as well, PET/MRI is likely to have a significant impact on the imaging evaluation of pediatric oncology patients.[87]

In addition to PET scanning, conventional γ-emission planar and SPECT imaging is still an important element of pediatric oncology imaging.[88-90] In particular, ^{123}I-metaiodobenzylguanidine (MIBG) and technetium-99m (^{99m}Tc)-methylene diphosphonate (MDP) bone scintigraphy are routinely used in the evaluation of neuroblastoma patients.[91] Bone scintigraphy is also an important component of the sarcoma patient evaluation.[90] As with PET scanning, SPECT images can be fused to anatomic data acquired by either CT or MRI in order to provide correlative information and to confirm sites of abnormality and clarify areas of equivocal disease.[92] Integrated SPECT/CT systems are also available, which allows both SPECT and CT images to be acquired concurrently. Attenuation and scatter correction techniques can be used to further optimize SPECT image quality and potentially reduce tracer dose, as well as improve the accuracy of lesion colocalization.[93] In many instances performing the SPECT and CT simultaneously may also obviate the need for two sedations, further enhancing patient safety and the overall imaging experience.

STAGING CONSIDERATIONS

A detailed discussion of the different staging classifications used in pediatric oncology is beyond the scope of this chapter. Specific staging considerations are discussed in the disease-specific chapters elsewhere in this text. It is important to note, however, that there are unique staging systems in pediatric oncology, such as the International Neuroblastoma Staging System (INSS), the Wilms tumor staging system, the Hodgkin lymphoma staging system (Ann Arbor Staging), the non-Hodgkin lymphoma staging system (St. Jude Classification), and the Pretreatment Extent of Disease (PRETEXT) staging system for hepatoblastoma. Because these different staging systems do not simply rely on tumor size and nodal spread in determining disease stage (i.e., tumor-nodes-metastasis [TNM] staging), the imaging evaluation must be tailored to reflect the type of malignancy being evaluated. The radiologist should work closely with the oncologist during the review of the initial imaging data in order to accurately determine the patient's disease stage and risk classification.

CENTRAL NERVOUS SYSTEM TUMORS

Primary CNS malignancies are the most common pediatric solid tumors, exceeded only by leukemia as a cause of pediatric cancer.[94,95] Although many of the pediatric CNS tumors are also seen in adults, there are several tumors that are unique to infancy and childhood and have characteristic imaging features and intracranial locations. The imaging evaluation should be directed at characterizing the location of the lesion (supratentorial or infratentorial) and determining whether the lesion is intraaxial or extraaxial. CT is usually the first imaging study performed to investigate children with suspected CNS tumors. Although the role of CT has been diminished by the increased use of MRI for imaging the brain, CT is still widely available and readily accessible in nearly all institutions. CT can effectively identify foci of hemorrhage or necrosis and can identify critical abnormalities such as brain edema or impending brain herniation. CT may also provide clues as to the histologic nature of the tumor, for example showing either a cystic or solid mass or the presence of subtle calcifications. Bone invasion into the adjacent skull is typically better depicted by CT, and particularly lesions at the base of the skull should include an evaluation by CT.

MRI of the brain, as with other parts of the body, provides enhanced spatial resolution and, with the variety of newly developed pulse sequences and imaging coils, can give highly specific functional and anatomic information about the lesion in question and the condition of the surrounding brain.[52,96] MR angiography can be performed during the same imaging evaluation and allows assessment of both arterial and venous systems. Obstruction to CSF flow can also be directly evaluated by MRI using specialized techniques aimed at monitoring CSF flow dynamics.

As described, advanced imaging techniques including MR spectroscopy, fMRI, and DTI[52] allow biochemical and metabolic characterization of focal lesions, assessment of functional activity in the brain, and direct evaluation of the structural integrity of CNS white-matter tracts, respectively. FDG-PET and PET scanning with newer radiotracers such as ^{18}F-thymidine may also be of additional value in delineating postsurgical margins from residual tumor and in predicting response to therapy.[97,98]

There are several classification systems for pediatric brain tumors. The most commonly used World Health Organization (WHO) classification of intracranial tumors is based on histopathologic characteristics and clinical course, with tumors further classified based on their intracranial location, specifically whether lesions are supratentorial or infratentorial. This classification system both allows a practical assignment of differential diagnoses to new CNS tumors based on their location and provides prognostic information related to histologic subtype and grade when this additional data becomes available.

Supratentorial Tumors

Astrocytomas

The most common supratentorial brain tumor is the astrocytoma, representing between 50% and 60% of all primary pediatric brain tumors.[99] Astrocytomas are seen in all age groups, and presenting symptoms are typically of intracranial pressure, with headache, nausea, and vomiting commonly seen. Astrocytomas can be reliably diagnosed by CT and MRI (Fig. 66-9). They range from benign to malignant in their histologic grade, with grade 1 lesions classified as benign, grade 2 as low-grade glioma, grade 3 as anaplastic glioma, and grade 4 as glioblastoma. The lesions are usually quite large with both solid and cystic components. Calcifications can occur but are unusual. Parietal, frontal, and temporal lobes are common sites of astrocytoma. On fluid-sensitive sequences, the cystic component of the lesion may show features of complex fluid, with decreased signal intensity relative to CSF on T2-weighted sequences. After contrast infusion, homogeneous enhancement of the solid component of the lesion is characteristic. Higher-grade, more malignant tumors often have less distinct margins, more heterogeneous enhancement, and increased peritumoral edema and mass effect.[100] Newer techniques including perfusion-weighted MRI and MR spectroscopy have been evaluated as noninvasive techniques to determine tumor angiogenesis and capillary permeability. For example, in higher-grade gliomas increased blood flow to the tumor lesion has been demonstrated using this technique.[101] Also, as the tumor grade increases to a more malignant variant, there is an increase in the Cho-to-NAA ratio, reflecting the increased metabolic activity present in higher grade lesions.[101,102] Complete surgical resection is often not possible because of involvement of adjacent major neural structures. The 5-year survival rate for low-grade astrocytomas is between 40% and 50%, with less than 5% survival for the higher-grade malignancies. Because of a propensity to spread to the spine via the CSF, the staging evaluation must also include imaging of the entire spine.

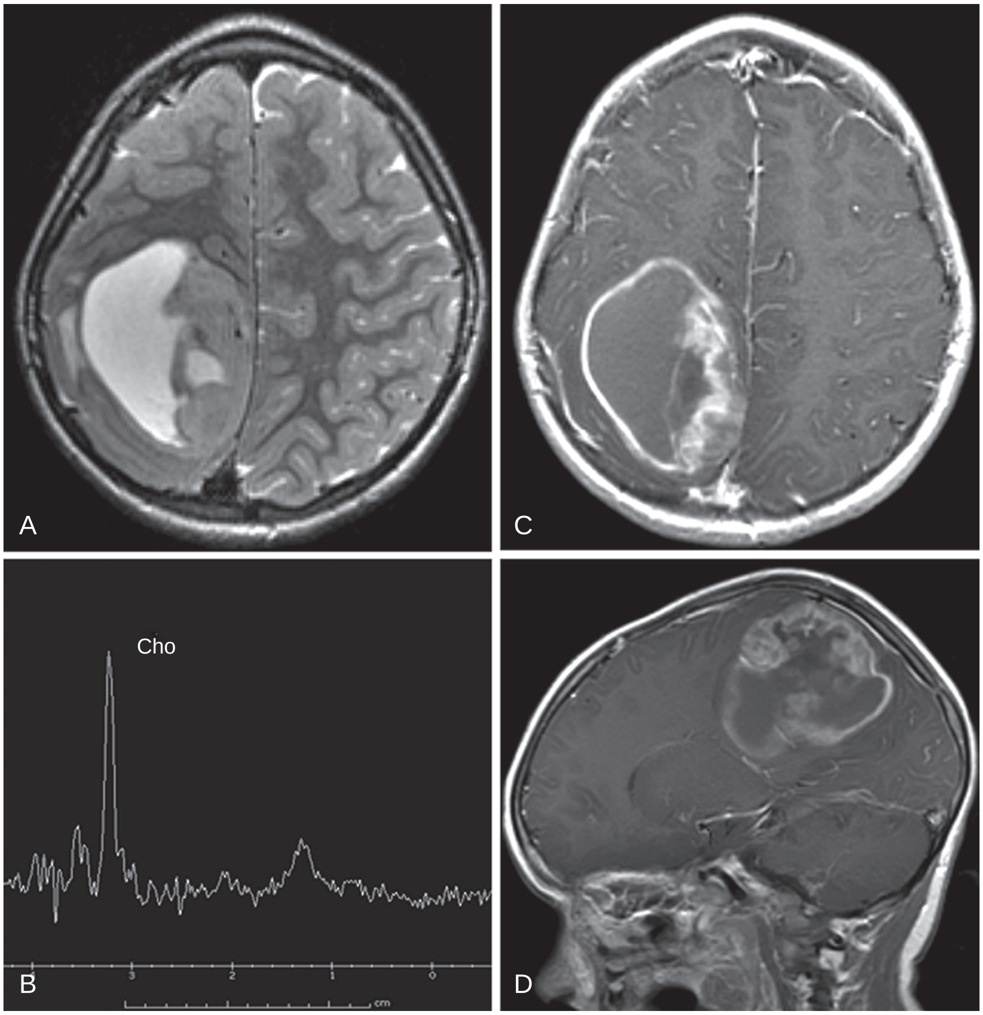

Figure 66-9 A 4-year-old patient with hemispheric astrocytoma. T2-weighted (**A**) and post-Gd T1-weighted images (**C** and **D**) show cystic and solid mass with peripheral enhancement located in the frontoparietal region. MRS from the solid component is notable for decreased N-acetylaspartate and elevated choline *(Cho)* and lipid peaks, typical of a highly cellular tumor (**B**).

The infratentorial/cerebellar form of astrocytoma, also known as *juvenile pilocytic astrocytoma,* is distinct from the diffuse supratentorial astrocytoma discussed here and is described in further detail below.

Oligodendrogliomas

Oligodendrogliomas, although common in adults, are relatively rare in children and adolescents.[103] The most common location is in the frontotemporal region, with less common involvement of the posterior fossa and spinal cord. Imaging evaluation shows a hypodense lesion on CT. Because the majority of these contain varying degrees of calcification, they are distinct as being the most common supratentorial tumor in childhood to calcify. The noncalcified solid component is typically isodense to the adjacent brain on CT. On MRI, the lesions are characterized by low signal intensity on T1-weighted images, hyperintensity on T2-weighted images, and minimal enhancement after infusion of gadolinium contrast (Fig. 66-10). Although these tend to be slow growing lesions, depending on their size there may be edema evident in the surrounding brain.

Gangliogliomas

Gangliogliomas and ganglioneuromas comprise about 5% of the pediatric brain tumors.[99] As with their counterparts in the peripheral nervous system, calcification is seen in up to 40% of the cases. The temporal lobes, frontoparietal lobes, and hypothalamic regions are the most common sites of involvement. The brainstem, posterior fossa, and spinal cord are less commonly involved. MRI demonstrates a low signal-intensity lesion on T1-weighted images with hyperintensity on T2-weighted images and hyperintense homogeneous enhancement after gadolinium infusion (Fig. 66-11).

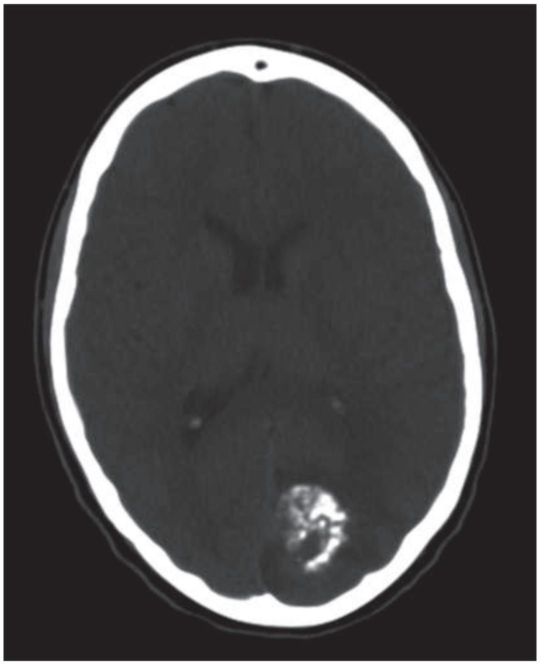

Figure 66-10 Oligodendroglioma. CT showing calcified low-attenuation lesion in the occipital cortex, with imaging features characteristic of oligodendroglioma.

Tumors of the midline deep gray matter, including the basal ganglia, thalamus, hypothalamus, and chiasmatic/optic pathway region tend to be astrocytomas.[95,104] As with the cerebral hemispheric astrocytomas, tumor grades range from benign to highly anaplastic. The imaging features are similar to the lesions located in the cerebral hemispheres with decreased signal intensity on T1-weighted images, hyperintensity on T2-weighted images, and variable contrast enhancement. Because of their location, behavioral changes, emotional and memory changes, movement disorders, visual abnormalities, and hydrocephalus are all common symptoms associated with these deep gray-matter tumors. Surgical resectability is often not possible, and the imaging evaluation is directed at identifying involvement of adjacent critical structures and monitoring posttherapy changes.[95]

Intraventricular tumors include choroid plexus papillomas, neurocytomas, and dermoid/epidermoid tumors. Choroid plexus papillomas/carcinomas are relatively common, making up between 10% and 20% of the intraventricular tumors identified in the first year of life and comprising approximately 5% of all CNS neoplasms.[103] The imaging features are characteristic and typically reveal large lobulated intraventricular lesions (Fig. 66-12). These tumors are highly vascular and are often associated with calcification and occasionally hemorrhage.[100,104] Depending on the size and location of the lesion, there may be obstructive hydrocephalus. MRI shows a low signal-intensity lesion on T1-weighted images with variable hyperintensity on T2-weighted images. Magnetic susceptibility is seen if hemorrhage is present, and after contrast infusion these lesions typically show marked contrast enhancement. The combination of a lobulated, intensely enhancing intraventricular lesion is nearly diagnostic of choroid plexus papilloma. Five percent to 10% of these lesions degenerate into choroid plexus carcinomas,[104] and this latter diagnosis is suggested by accompanying necrosis within the lesion and metastatic spread into the adjacent brain, either by direct extension into the adjacent brain or by CSF dissemination. Because of their intraventricular location, metastatic spread throughout the CNS via CSF dissemination is unfortunately common for choroid plexus carcinomas, resulting in a uniformly poor prognosis.[95]

Central Neurocytomas

Neurocytomas are rare in children and have imaging features that mimic oligodendroglioma, showing an intraventricular calcified mass with heterogeneous contrast enhancement. These tumors typically involve the lateral ventricle in the midline; however, surgical resection is necessary to distinguish this lesion from other intraventricular tumors such subependymal astrocytomas and ependymomas.

Midline Supratentorial Tumors

Tumors of the hypothalamic/suprasellar region include craniopharyngiomas, hypothalamic hamartomas, and pineal region tumors.

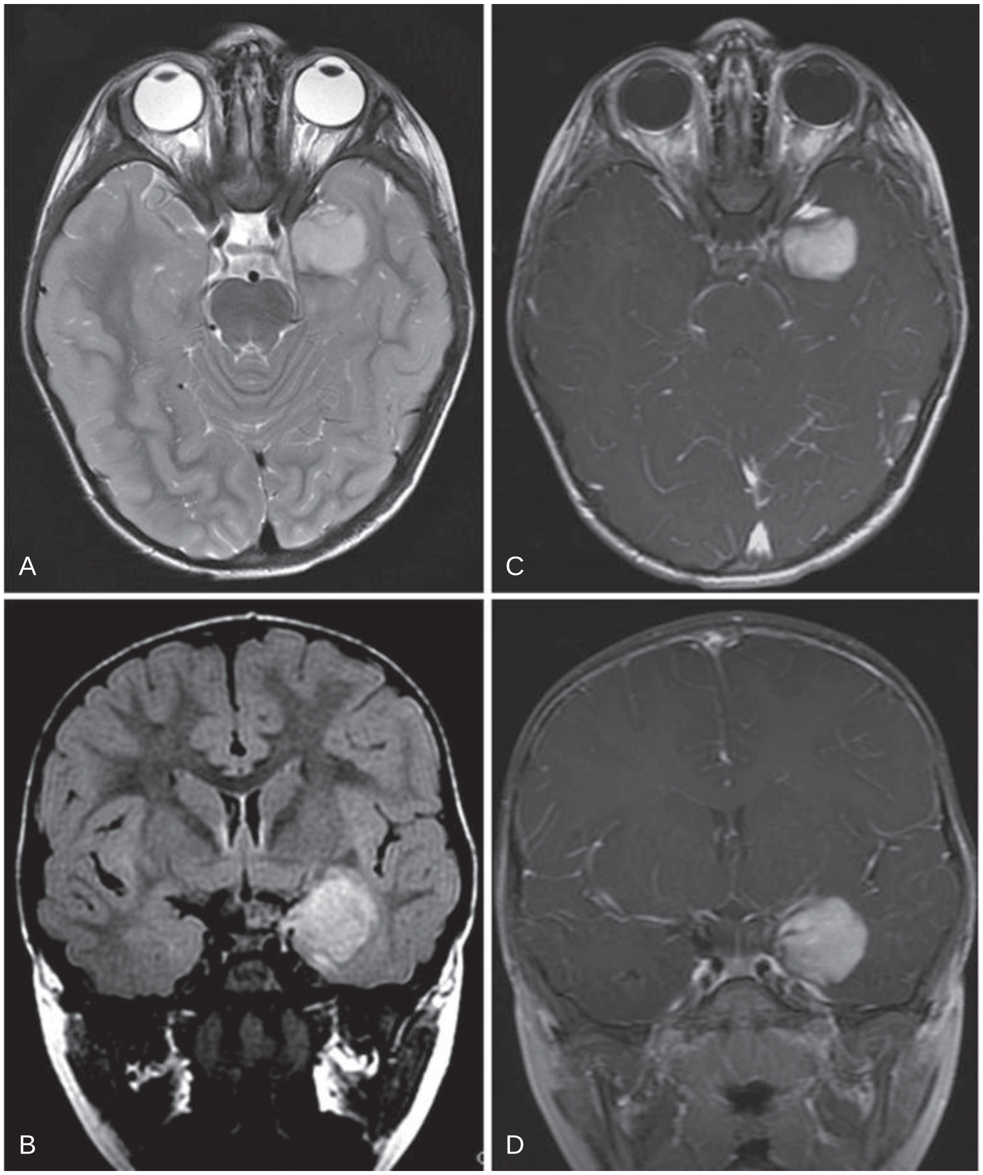

Figure 66-11 Ganglioglioma. A 4-year-old patient with left temporal-lobe ganglioma showing increased signal on T2-weighted images (**A**), and bright enhancement after gadolinium administration (**C** and **D**). Depending on their location, these lesions may be more conspicuous on fluid-attenuated FLAIR images (**B**).

Craniopharyngiomas

Craniopharyngioma is the most common suprasellar tumor.[100,104,105] It has fairly characteristic imaging features with lesions containing solid, cystic, and calcified elements. Symptoms usually result from increased intracranial pressure and local effects upon the hypothalamic pituitary region and optic chiasm. Because these are relatively slowly growing lesions, they may be quite large at diagnosis. The presence of a calcified suprasellar mass at CT scan is usually suggestive of the diagnosis; however, MRI is superior in evaluating the extent of involvement (Fig. 66-13). Depending on the type of material present in the cystic component of the mass, variable signal intensity on T1- and T2-weighted images may be seen.[106] It is common, for example, for the complex proteinaceous, cholesterol-laden fluid to be variably hyperintense on both T1- and T2-weighted images (see Fig. 66-13). After contrast infusion, the cyst wall commonly enhances. However, the solid components of the cyst often demonstrate inhomogeneous enhancement as well. Of note, craniopharyngiomas commonly cause T2 prolongation along the optic tracts. This is a nonspecific sign and has been reported in other tumors centered in this region. It is thought to signify optic tract edema caused by compression by the tumor.[107]

Pineal-Region Tumors

Pineal-region masses are characterized by their location in the quadrigeminal plate cistern. These tumors typically arise from primordial germ cells and include pineoblastomas, pineocytomas, and immature germ-cell tumors.[95,100,103,104] It is important to distinguish these

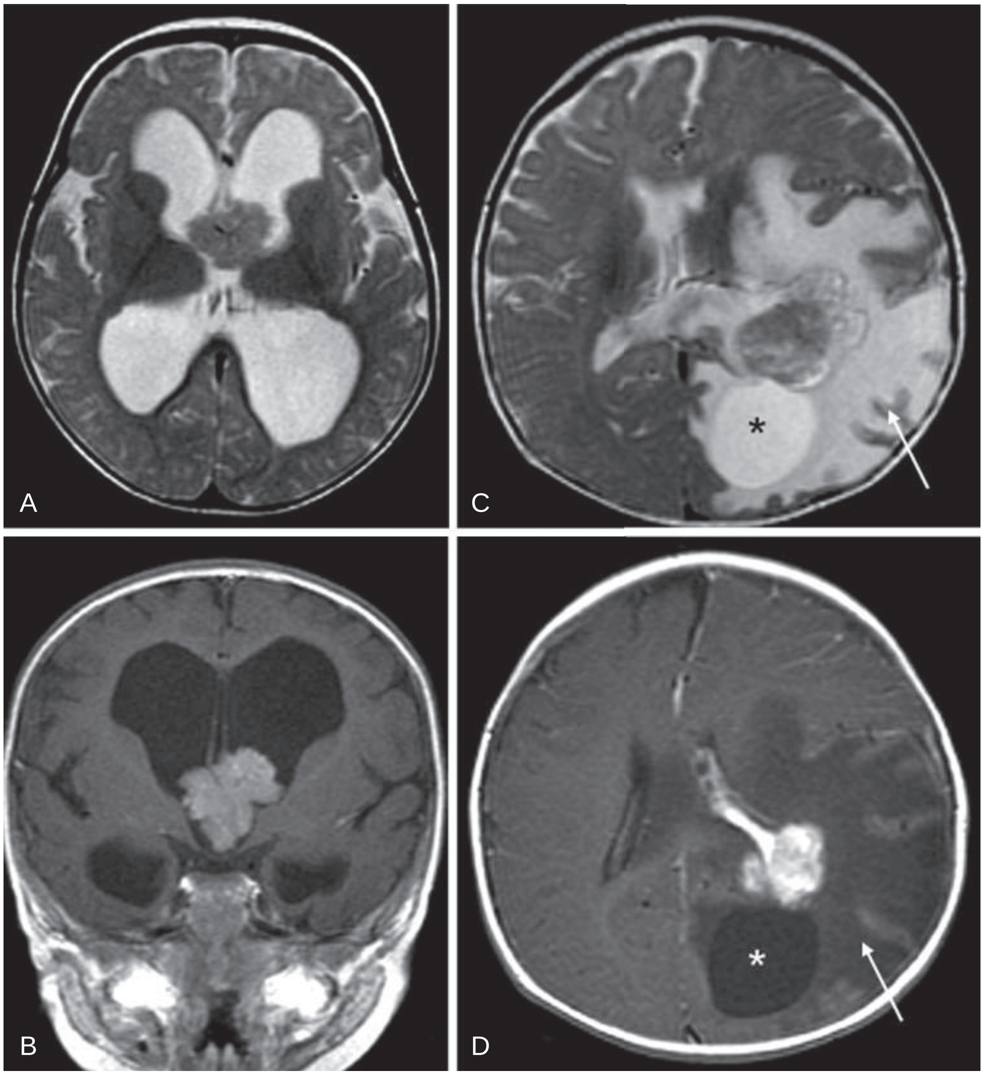

Figure 66-12 Choroid plexus papilloma. 8-month-old and 10-month-old infants, both with large lobulated lesions causing obstructive hydrocephalus. **A** and **B**, In one patient the tumor is centrally located, producing severe global hydrocephalus. **C** and **D**, In the other patient the peripheral location is accompanied by extensive vasogenic edema *(arrow)* and left occipital-horn hydrocephalus *(asterisk)*.

neoplastic lesions from benign pineal cysts, which are commonly seen within the pineal gland. Pineal cysts have a characteristic appearance on both CT and MRI and do not distort or compress the adjacent ventricles. Simple pineal region cysts typically do not achieve sizes greater than 1 cm. Also of note is normal calcification within the pineal gland. Calcification is unusual before the age of 10 but is commonly seen in adolescents and older children.[108] Therefore the presence of calcification in the pineal region in an infant or young child should raise suspicion for a pineal region mass/germ-cell tumor and prompt further investigation.

Pineal-gland tumors, including pineocytomas and pineoblastomas, are relatively rare. Pineocytoma is benign and usually nonaggressive, whereas the pineoblastoma, representing an immature undifferentiated lesion, often metastasizes. Pinealoblastoma is also a component of the "trilateral retinoblastoma" and is seen with increased incidence in patients diagnosed with bilateral retinoblastoma. Pineocytomas are more often more calcified than pinealoblastomas. Pinealoblastomas are typically larger with low signal intensity on T1-weighted images, variable hyperintensity on T2-weighted images, and fairly homogeneous contrast enhancement (Fig. 66-14).[109] Very large pinealoblastomas frequently produce mass effect on the adjacent quadrigeminal cistern, and because of their large size often show areas of necrosis.

Germ-Cell Tumors

The pineal region is the most common location for intracranial germ-cell tumors.[110,111] Histopathologically these are most often germinomas and are usually associated with calcification. This is well demonstrated by CT. MRI is indicated to better delineate the extent of the noncalcified solid portion of the mass as well as heterogeneous cystic portions that may also be present. On T2-weighted images, the solid portion is typically hyperintense with bright enhancement after contrast infusion. Other tumors

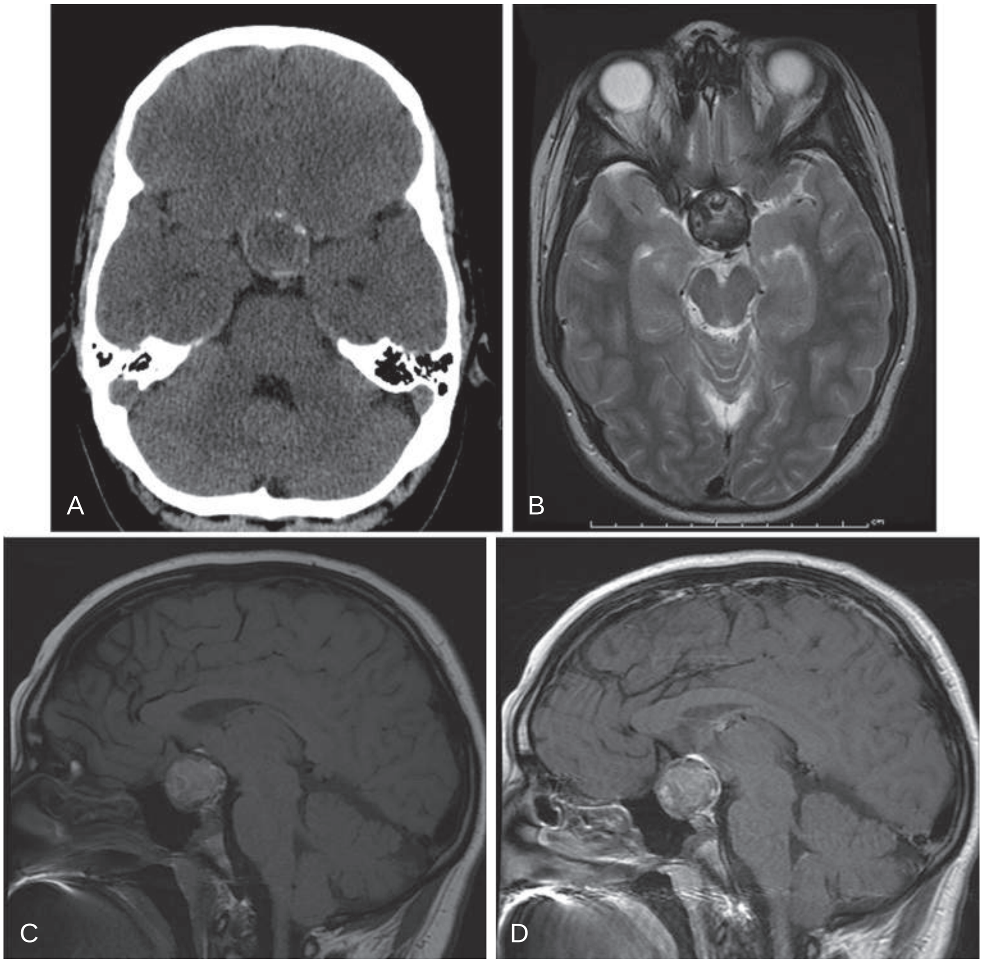

Figure 66-13 Craniopharyngioma. CT showing calcified suprasellar mass (**A**), with heterogeneous increased signal on both T2-weighted images (**B**) and T1-weighted images (**C**), with peripheral enhancement after gadolinium (**D**).

of germ-cell origin are also seen, with choriocarcinomas more commonly showing hemorrhagic components and displaying more aggressive features. Benign teratomas, in contrast, display imaging features more in keeping with their well-differentiated dermoid/epidermoid components, including low attenuation fluid on CT, hyperdense fluid on T1-weighted sequences, and heterogeneous contrast enhancement (Fig. 66-15).

Hypothalamic Hamartoma

This is a rare congenital lesion, usually identified in infants under the age of two. Seizure disorders are common, and these patients often have the presenting symptoms of intractable gelastic seizures. The presence of precocious puberty or diabetes insipidus may provide clinical clues to suggest this diagnosis.

On imaging, CT scanning shows an isodense mass in the region of the hypothalamus. There is little to no contrast enhancement either on CT or MRI.[112] On MRI, the lesion is usually isodense to the brain on T1-weighted images, minimally hyperintense on T2-weighted images, and interestingly may be hyperintense on FLAIR images (Fig. 66-16). Because of the location of these tumors, surgical resection may be challenging, and MR- or CT-guided ablation techniques are now increasingly being used (Fig. 66-17).

Infratentorial Tumors

The most common lesions of the posterior fossa/cerebellum are juvenile pilocytic astrocytomas (JPAs) and medulloblastomas.[99]

Medulloblastomas

Medulloblastomas are slightly more common in incidence than cerebellar astrocytomas.[95] They typically occur in the first decade of life. Presenting symptoms usually relate to increased intracranial pressure secondary to obstructive hydrocephalus, most often related to mass effect upon the fourth ventricle. Medulloblastomas are highly malignant and have a propensity to disseminate and seed the CNS via the CSF route.[103] Hematogenous spread to other sites may also occur in medulloblastoma.

CT scanning is usually the first imaging study performed to evaluate new-onset nausea, vomiting, headache, or seizures. CT scanning usually demonstrates a hyperintense solid lesion within the cerebellum, often

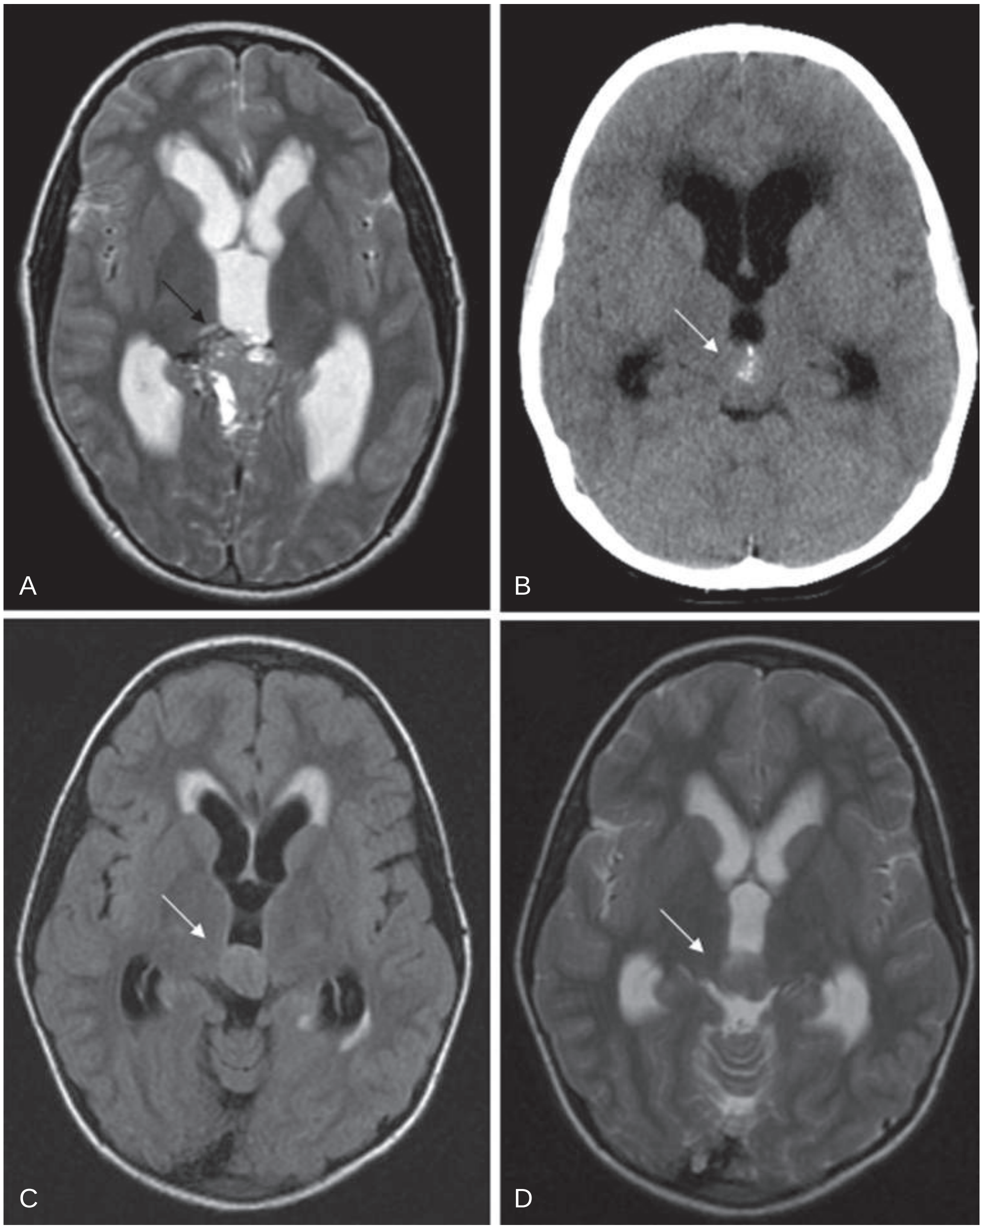

Figure 66-14 Pinealoblastoma. Two patients with pinealoblastoma. The larger cystic/solid mass seen in one patient causes obstruction and hydrocephalus at the level of the quadrigeminal plate cistern (**A**). In the accompanying case (**B**), even the smaller calcified mass causes hydrocephalus as a result of its central location abutting the ventricles. As noted in the text the lesions are often hyperintense on fluid-attenuated sequences (**C**, *FLAIR images*) and isointense to cortex on T2-weighted images (**D**).

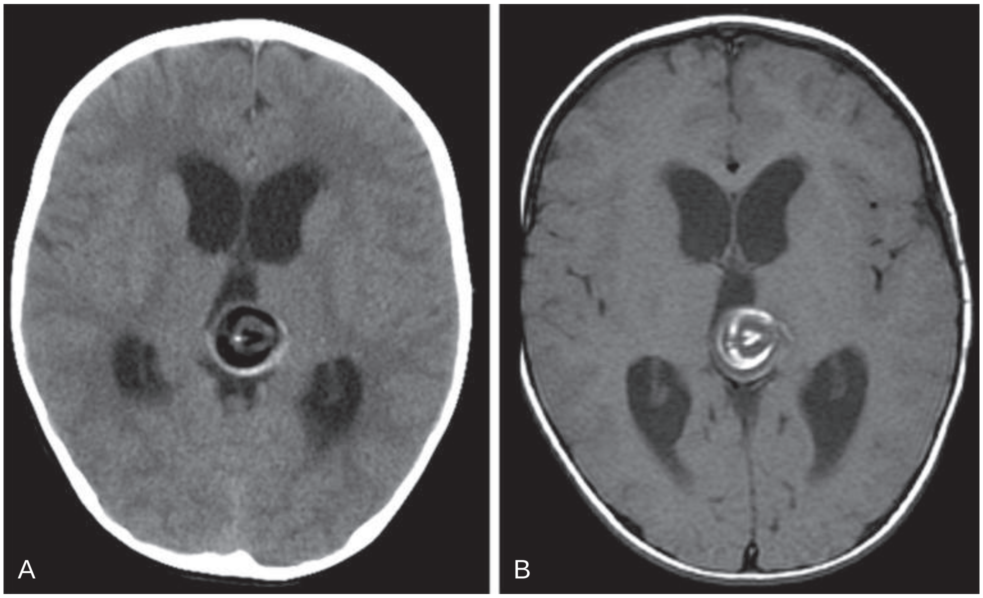

Figure 66-15 Pineal germ-cell tumor. CT (**A**) and T1-weighted axial MRI (**B**) showing low attenuation fluid on CT and hyperintense fluid on T1-weighted sequences, typical of a well-differentiated pineal germ-cell tumor (teratoma).

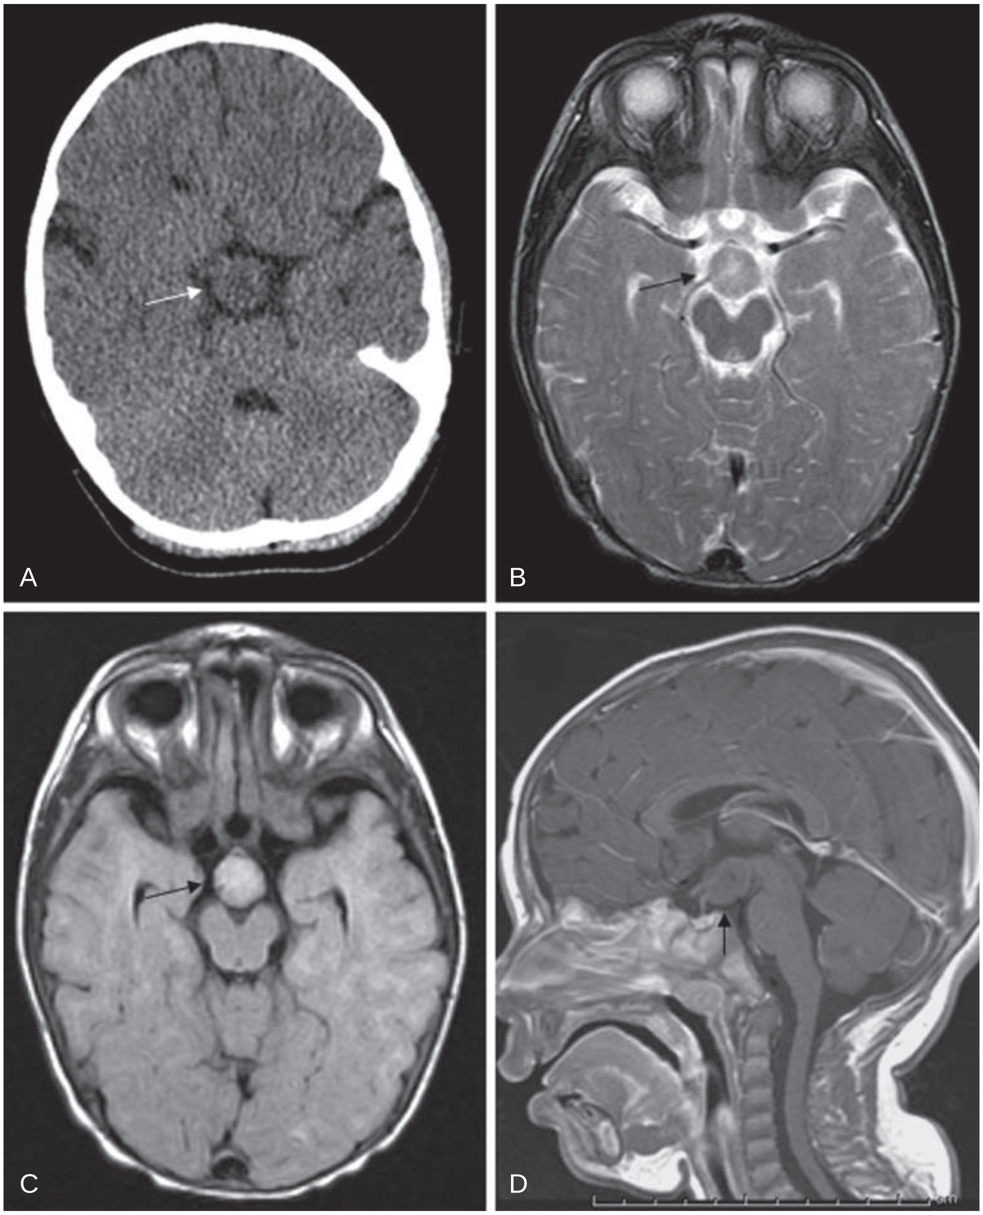

Figure 66-16 Hypothalamic hamartoma. **A**, CT shows a low density suprasellar/hypothalamic lesion. MRI shows the lesion to be isointense to brain on T2-weighted sequences (**B**), mildly hyperintense on FLAIR images (**C**), with no significant enhancement after gadolinium infusion (**D**).

near the midline (Fig. 66-18). MRI imaging is indicated to better characterize the lesions and to establish sites of local and metastatic spread. As with other highly cellular CNS tumors, on T1-weighted images medulloblastomas are usually hypointense relative to the adjacent cerebellum, with increased signal intensity on T2-weighted images (see Fig. 66-18) and homogeneous enhancement after gadolinium infusion.[100,104] Calcification and cystic areas are unusual in medulloblastoma. Because of the propensity to disseminate to other sites via the CNS, the staging evaluation must include a contrast-enhanced evaluation of the entire spine.

Cerebellar Astrocytomas

Astrocytomas are the next most common posterior fossa tumor.[95,99] As with their intracerebral counterpart, cerebellar astrocytomas range in histologic grade from benign to anaplastic. The characteristic juvenile pilocytic form makes up the majority of the cerebellar astrocytomas. Both cystic and solid components are normally present in this type of astrocytoma (Fig. 66-19). Calcification is unusual and occurs in 10% of tumors.[113] After resection, survival is excellent with a 10-year overall survival rate greater than 90%. As with medulloblastoma, CT scanning is usually the first imaging modality used to evaluate initial symptoms. CT shows a heterogeneous, predominantly cystic lesion in the posterior fossa, typically with a small mural nodule eccentrically along the margin of the tumor. These lesions are often midline, near the vermis, but may also be eccentric in location. MRI imaging is indicated to better characterize the extent of cerebellar involvement. Although the presence of a

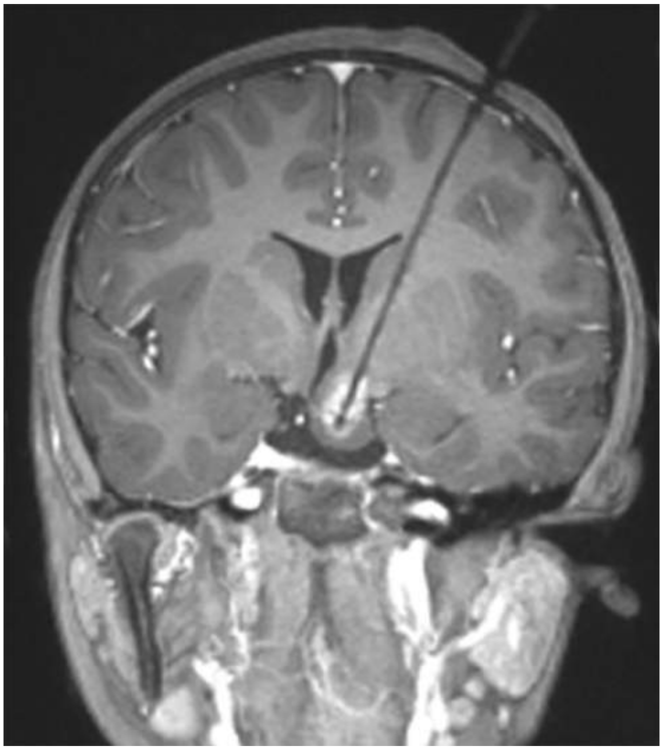

Figure 66-17 MRI-guided laser ablation of hypothalamic hamartoma in a 4-year-old female with medically intractable gelastic seizures. Coronal reformat of a magnetization-prepared rapid acquisition with gradient echo shows the needle tip within the lesion in the hypothalamus with enhancement around the tip indicating the areas that have been ablated by the procedure.

predominantly cystic component suggests a lower-grade neoplasm, foci of local/metastatic spread may be present and will be manifest as a focus of increased enhancement after contrast administration.[103] Therefore the imaging evaluation should include conventional T1- and T2-weighted imaging as well as postcontrast enhanced scanning in all three imaging planes. Because higher-grade neoplasms may also disseminate via the CSF, as with medulloblastoma, the initial staging evaluation should also include evaluation of the entire spine.

Brain-Stem Gliomas

Brain-stem gliomas make up the majority of the neoplasms involving the brain stem. These tumors are of astrocytoma origin and because of their location result in nearly uniformly poor survival.[95] These predominantly cellular solid lesions are best evaluated by MRI, and they typically appear as hypodense lesions on T1-weighted images, with increased signal intensity on T2-weighted images, and show heterogeneous enhancement.[100,103,104] Lower-grade lesions, or lesions with larger cystic components may only show very minimal contrast enhancement (Fig. 66-20). As with the other tumors in these locations, spread is most often via the CSF to other portions of the brain.

Ependymomas

After medulloblastomas and juvenile pilocytic astrocytomas, the next most common posterior fossa tumor is the ependymoma, constituting approximately 8% to 15% of intracranial neoplasms.[99] The majority of these tumors are benign and arise from the ependyma of the fourth ventricle. They typically present as a calcified intraventricular mass. Symptoms result from obstruction of CSF flow at the level of the fourth ventricle leading to obstructive hydrocephalus. There are two histologic types, with the

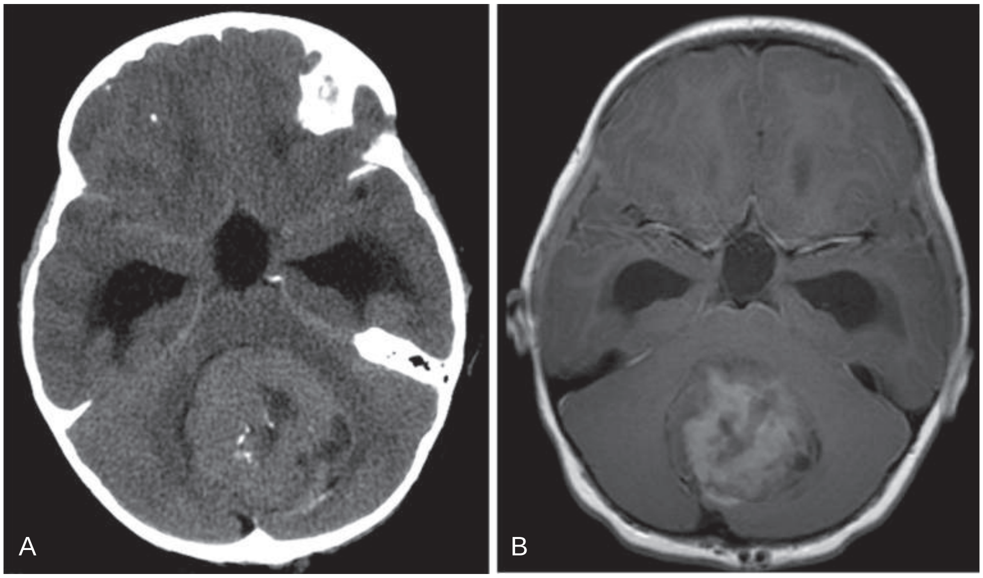

Figure 66-18 Medulloblastoma. **A**, Unenhanced CT shows hyperdense mass in the posterior fossa, compressing the fourth ventricle with resultant obstructive hydrocephalus. **B**, Gadolinium-enhanced T1-weighted MRI shows enhancement of the majority of the mass; these features are all consistent with a highly cellular medulloblastoma.

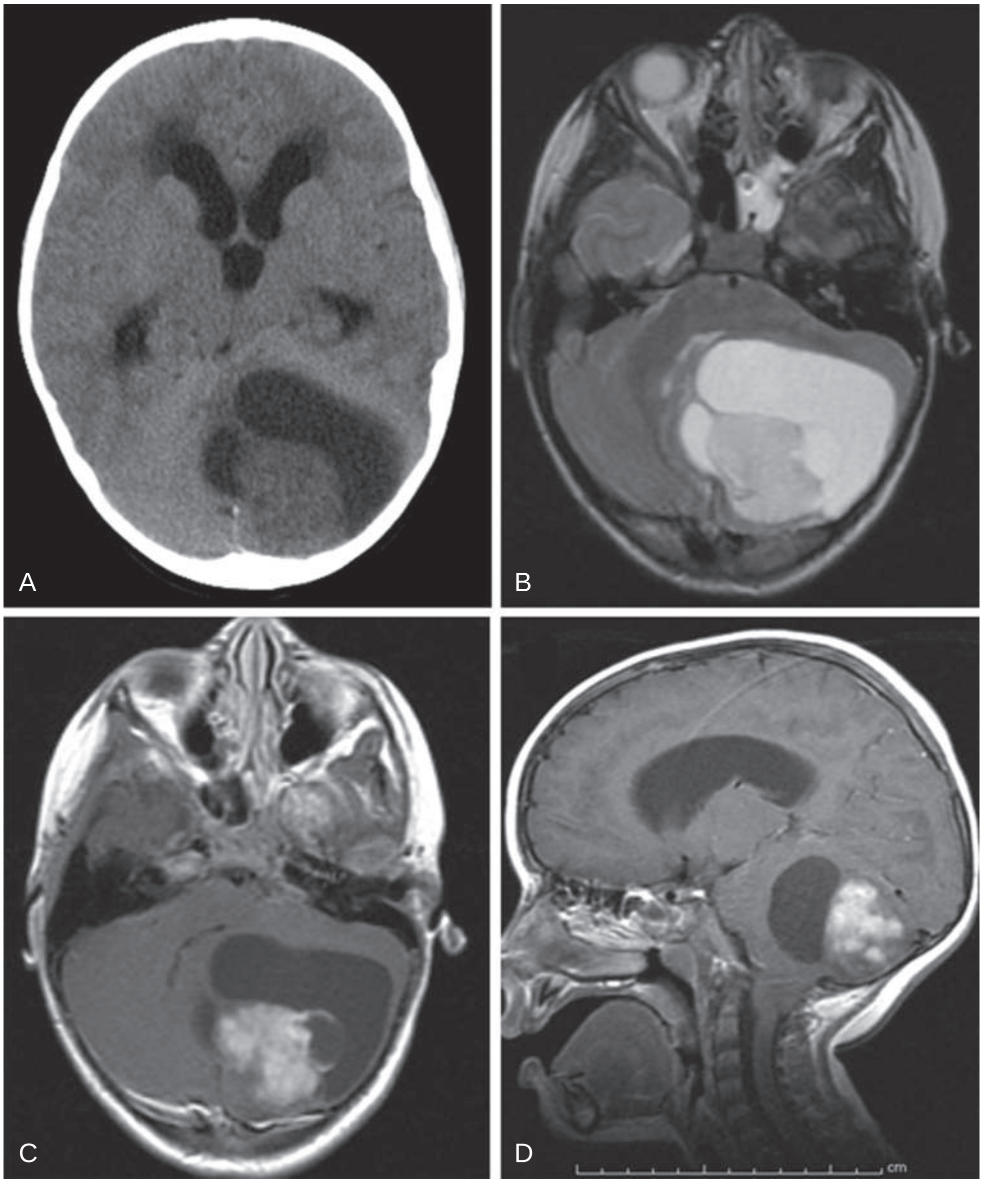

Figure 66-19 Cerebellar pilocytic astrocytoma. **A**, Unenhanced CT shows a large, predominantly cystic mass with a solid mural component in the posterior fossa with moderate hydrocephalus. **B**, T2-weighted MRI shows high signal-intensity cystic fluid and intermediate signal mural nodule. **C** and **D**, Only the mural nodule enhances after gadolinium infusion.

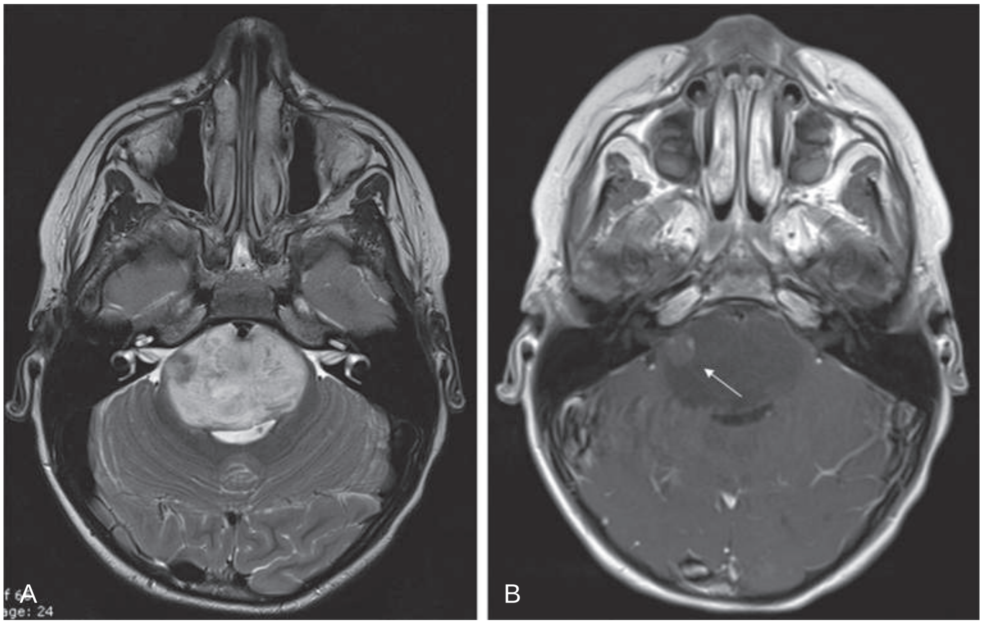

Figure 66-20 Low-grade pontine glioma. Axial T2 (**A**) and post-Gd T1-weighted (**B**) images show T2-bright lesion with faint enhancement of a small nodular component of the tumor along the lateral margin *(arrow)*.

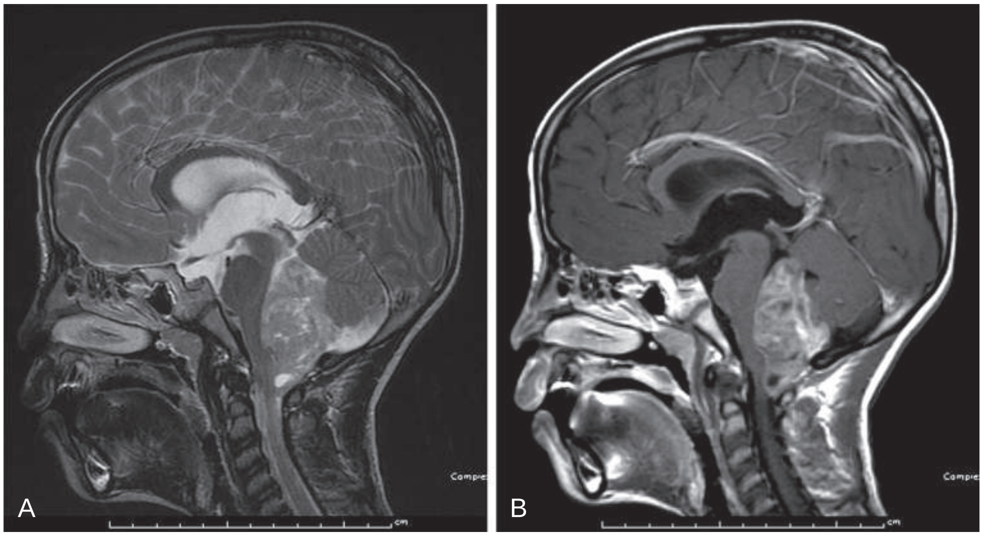

Figure 66-21 Ependymoma. A 7-year-old patient with the symptom of lethargy. T2-weighted (**A**) and gadolinium-enhanced (**B**) MRI show a large heterogeneously enhancing posterior fossa mass compressing the brain stem and beginning to extend out through the foramen magnum.

benign undifferentiated type more common, typically less invasive locally, and with a lower likelihood of CSF dissemination. Malignant anaplastic ependymomas, in contrast, tend to spread via the CSF early in the disease course to other sites within the CNS. Because of their propensity to insinuate through neural foramina, resulting in a lobulated appearance, ependymomas have a fairly characteristic appearance on imaging (Fig. 66-21). Depending on the degree of calcification, these lesions may be predominantly hypointense on T1- and T2-weighted images. In the absence of calcification, these are usually hyperintense lesions on T2-weighted images with heterogeneous intense enhancement after gadolinium infusion.[104] Because of their propensity to seed throughout the CSF and ventricular system, the imaging evaluation must include examination of both the brain and spinal canal.

Hemangioblastomas

Hemangioblastomas are benign vascular lesions that are more common in adults than children. However, the cerebellum is still the most common location in children, and multiple hemangioblastomas may be encountered in familial predisposition syndromes such as the von Hippel-Lindau disease.[114] The imaging features demonstrate a predominantly cystic lesion with an enhancing mural nodule that may be difficult to distinguish from JPAs. As with JPAs, these lesions show cystic characteristics on MRI with low signal intensity on T1-weighted images and T2 hyperintensity, with intense enhancement of the solid mural nodular component (Fig. 66-22). Depending on the size of the mural nodule, the degree of enhancement, and its location, these lesions may also be difficult to discriminate from a benign posterior fossa arachnoid cyst.

Metastatic Disease

Metastatic disease to the CNS may result from leptomeningeal seeding, hematogenous dissemination, or direct extension. Leptomeningeal seeding results from a number of primary brain tumors, most notably medulloblastomas.[115] Leptomeningeal seeding can also result from non-CNS primary tumors and systemic malignancies.[116] The imaging appearance in this setting is similar to that of leptomeningeal dissemination occurring secondary to a primary CNS tumor.

Hematogenous metastases to calvarium or dura are most commonly seen in patients with neuroblastoma, leukemia, and lymphoma. These lesions present as lytic calvarial lesions or as nonspecific, enhancing dural masses. CNS involvement by leukemia is also common, although this is more often diagnosed by lumbar puncture and pathologic evaluation of the CSF rather than imaging.

Hematogenously disseminated metastases to the brain parenchyma are rare in childhood. When they do occur, primary tumors are sarcomas, particularly rhabdomyosarcoma, Ewing sarcoma,[117] and osteosarcoma. A tumor with a particular propensity to metastasize to the brain is the rhabdoid tumor of the kidney, and imaging of the CNS is essential in children with this diagnosis. Parenchymal metastases are usually multiple and located at the interface between the gray and white matter. They are associated with marked vasogenic edema and demonstrate avid enhancement secondary to loss of the blood-brain barrier.

Although the imaging features may be variable depending on the primary malignancy, the presence of any focal area of signal abnormality or enhancement with a known primary tumor should raise suspicion for metastatic spread of disease to the CNS.

Spinal Cord Tumors

In comparison to pediatric brain tumors, spinal cord tumors are relatively rare in children. The majority of the intramedullary spinal tumors in children are low-grade astrocytomas, with the remainder being ependymomas.[118,119] The imaging features of these lesions mimic

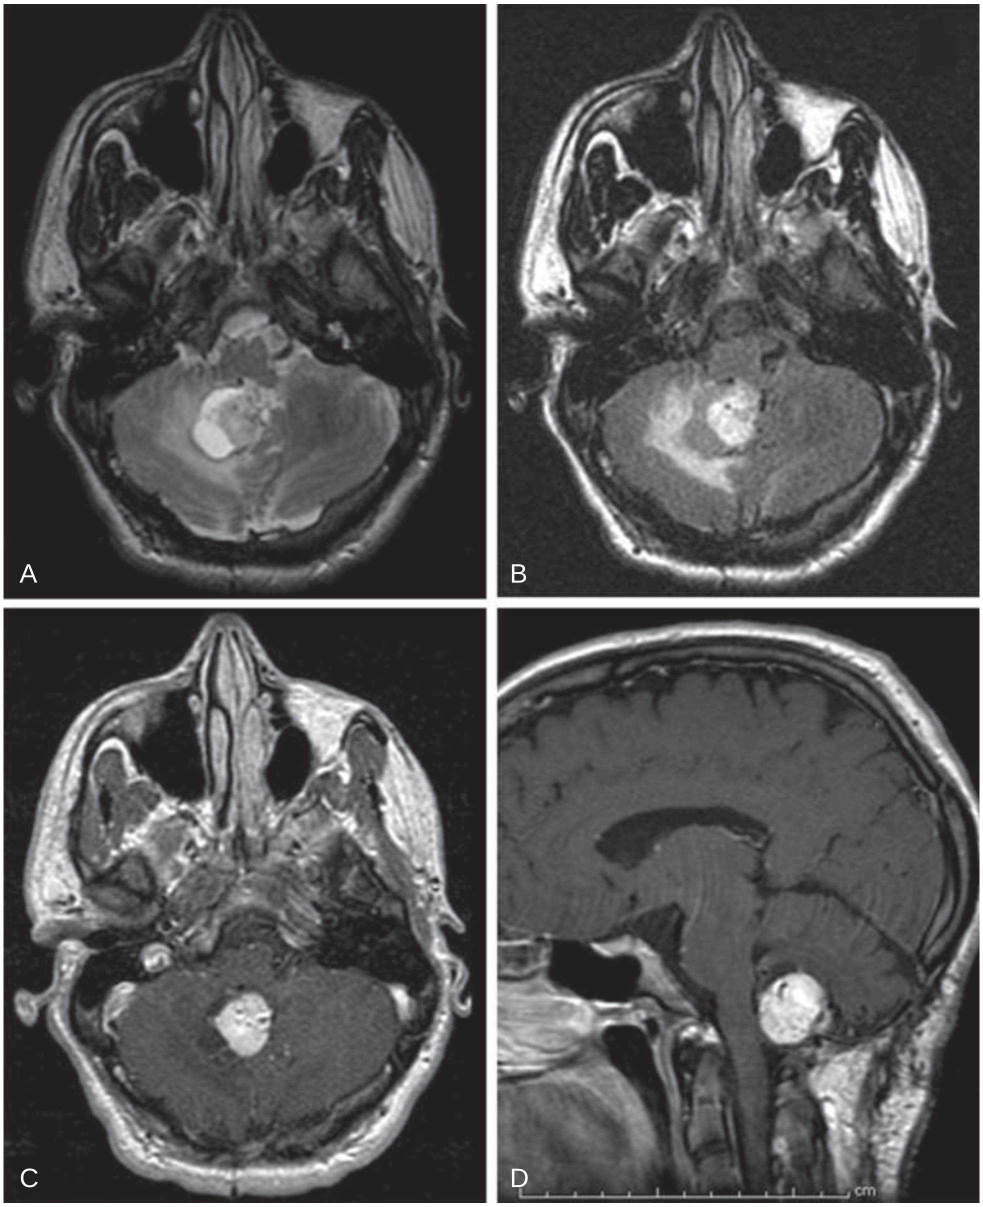

Figure 66-22 Hemangioblastoma. A 28-year-old patient with von Hippel-Lindau disease and cerebellar hemangioblastoma showing typical features on T2-weighted (**A**), fluid-attenuated FLAIR (**B**), and post-gadolinium enhanced images (**C** and **D**).

their intracranial counterparts. The imaging assessment is usually prompted by neurologic symptoms and should include multiplanar T1, T2, and post–gadolinium-enhanced imaging. Because it may be difficult to discriminate a primary intraspinal tumor from metastatic disease, imaging of the brain must also be performed.

As in the brain, the imaging examination should be directed at identifying the site of origin of the tumor. It should be possible to make a distinction between primary intramedullary tumors, extramedullary intradural tumors, and extradural/epidural lesions. This is important, because the majority of the spinal tumors in children are extramedullary. Intradural extramedullary lesions are, by definition, located within the subarachnoid space and are typically the result of drop metastases, which as discussed earlier, spread via the CSF from primary brain tumors (Fig. 66-23). Their appearance on imaging mimics their counterparts in the brain. Extradural extramedullary tumors may arise from local extension of other primary neoplasms such as neuroblastoma, lymphoma, or Ewing sarcoma (Fig. 66-24). In evaluating these other primary pediatric neoplasms, when their location is adjacent to the vertebral column, it is essential that a thorough imaging evaluation be undertaken to evaluate the presence and extent of intraspinal involvement. In particular, with neuroblastoma, this will influence staging and surgical resectability. The presence of intraspinal extension may be suggested by CT, but will be typically better delineated by MRI (Fig. 66-25).

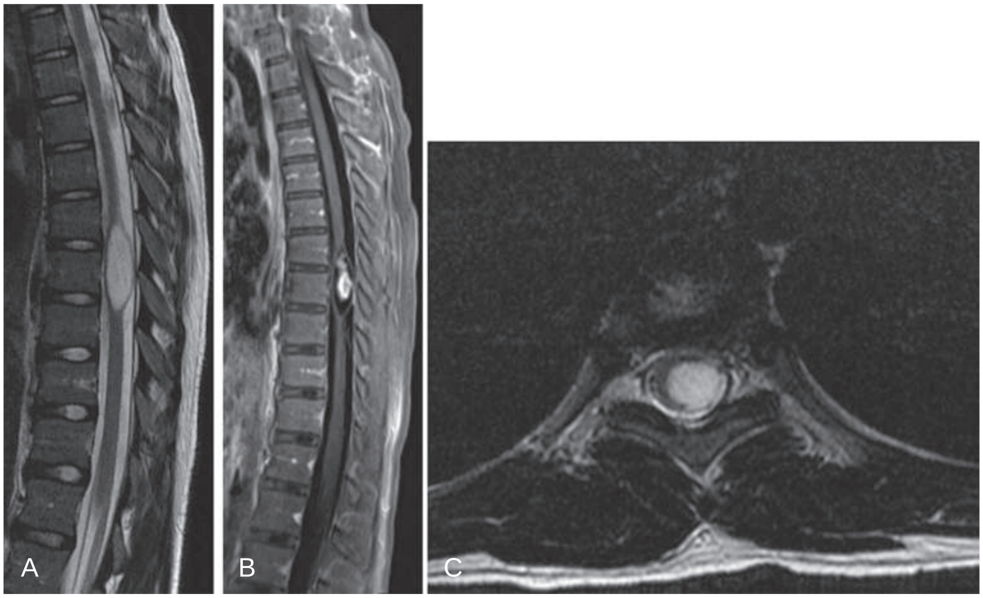

Figure 66-23 Spinal cord astrocytoma. Sagittal T2-weighted (**A**), sagittal post-Gd T1-weighted (**B**), and axial T2-weighted (**C**) images demonstrate a T2-hyperintense, ovoid lesion with enhancing central components consistent with a intramedullary thoracic spinal cord tumor. Pathology of resected specimen showed a low-grade astrocytoma.

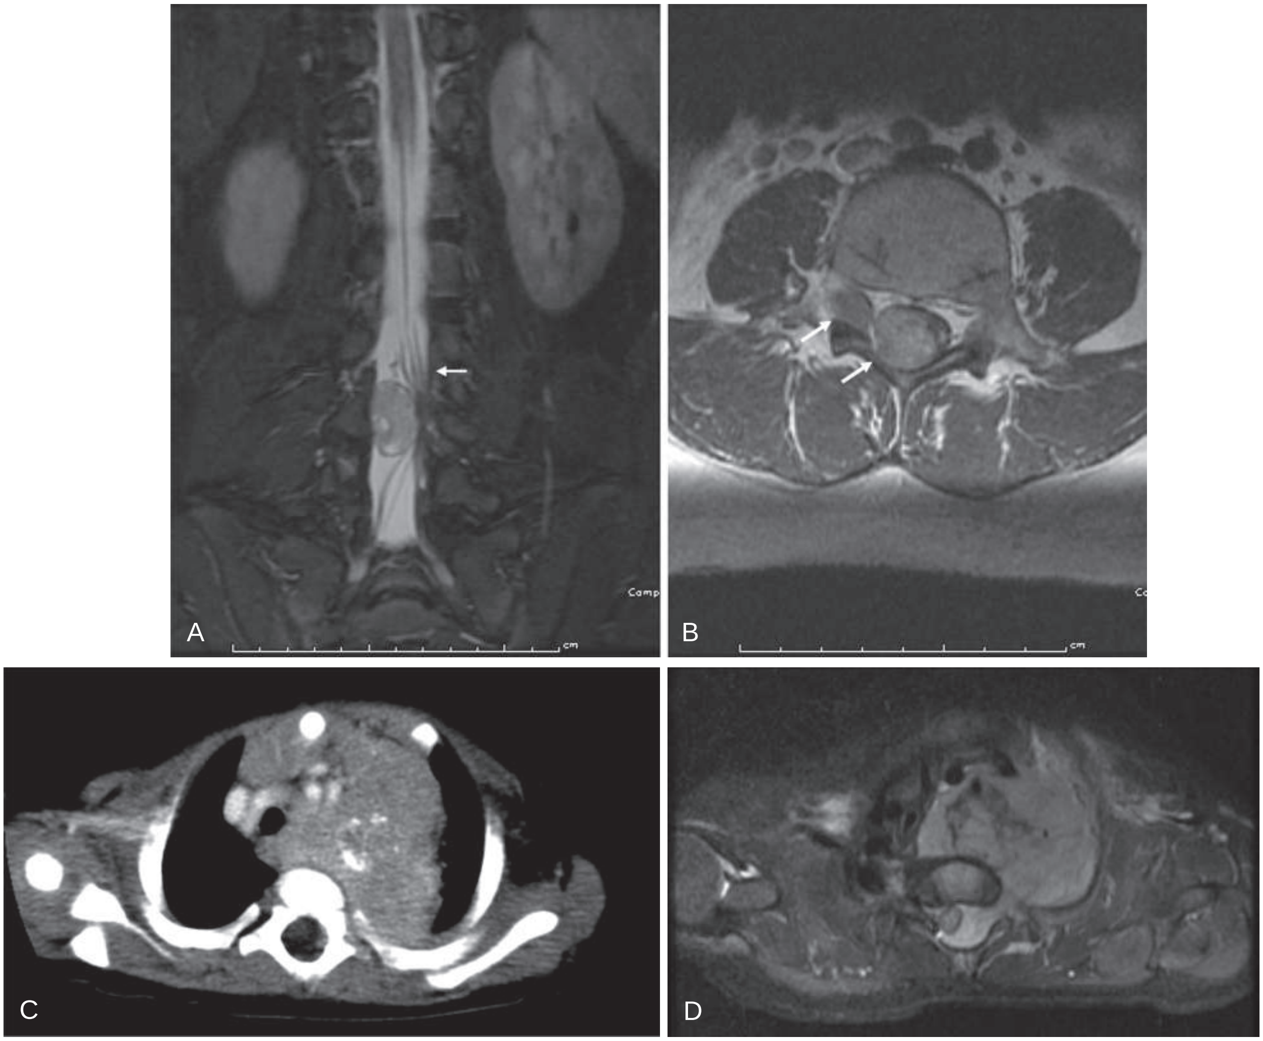

Figure 66-24 **A** and **B**, Coronal and axial MRI images show displacement of nerve roots and intension through the neural foramen in a patient with extramedullary intraspinal Ewing sarcoma. **C** and **D**, Patient with calcified left upper thoracic neuroblastoma initially detected on chest x-ray. MRI is superior in detecting the degree of intraspinal extension (**D**).

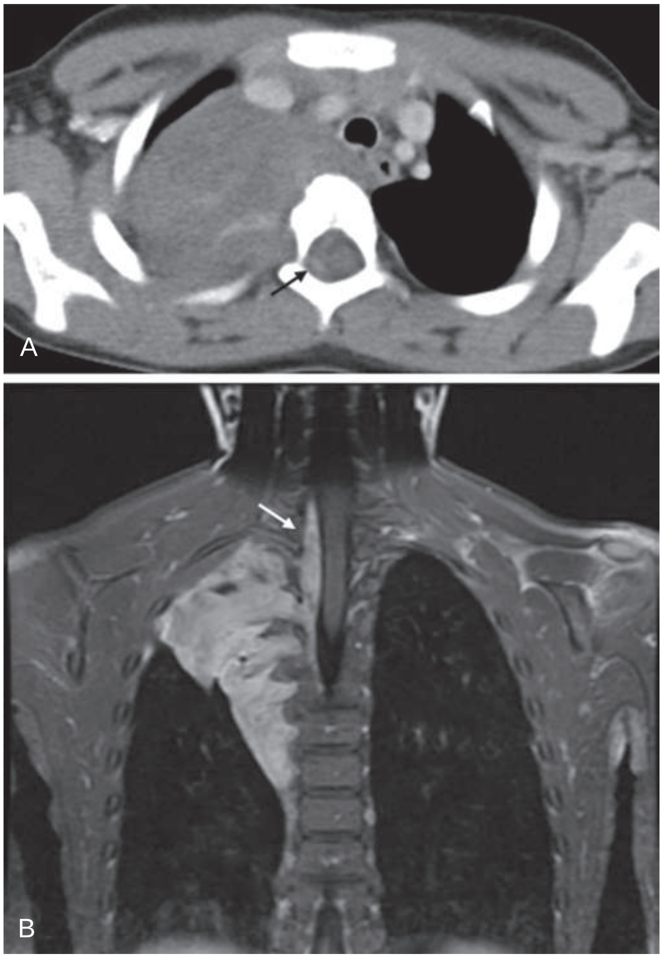

Figure 66-25 Upper thoracic paraspinal neuroblastoma. A 5-year-old patient with 2 weeks of upper-respiratory–infection symptoms. Chest x-ray revealed a right upper lobe opacity (not shown). This was found on CT to be a paraspinal mass. Intraspinal extension is evident on CT (**A**, *arrow*) but much better delineated by MRI (**B**, *arrow*).

PULMONARY AND INTRATHORACIC TUMORS

Thyroid and Parathyroid Tumors

Thyroid carcinoma in children is rare.[120] Three histologic subtypes are recognized in children, with the majority of patients (≈80%) having papillary carcinoma; follicular (≈15%) and medullary (≈5%) thyroid cancers occur less often. The risk is increased in patients with prior history or neck radiation or with predisposing familial syndromes (e.g., multiple endocrine neoplasia [MEN]).[120] Presentation is typically a painless mass in the thyroid gland. Ultrasound is the imaging modality of choice in evaluating the thyroid gland and is usually sufficient to characterize a palpable thyroid abnormality.[121] The goal of the ultrasound examination is to determine whether a cystic or solid mass is present (Fig. 66-26). The presence of increased flow and size of the mass is not reliable in distinguishing benign from malignant thyroid nodules. Malignant nodules are nearly always cold on ^{123}I-radioiodine scintigraphy relative to the surrounding thyroid gland.[121] Depending on the type of tumor, metastatic spread to adjacent lymph nodes and/or the lung may be present. In particular, papillary carcinoma of the thyroid often produces multiple small pulmonary nodules with a miliary distribution. These small pulmonary nodules may be challenging to detect by chest x-ray, and chest CT is indicated to provide increased sensitivity for lesion detection.[122] Bone metastases and thoracic lymph node involvement are common sites of extrapulmonary metastatic spread. ^{123}I or ^{131}I scintigraphy may also detect lesions not seen by conventional imaging (Fig. 66-27). The treatment of thyroid cancer in children includes total thyroidectomy and lymph-node dissection, followed by ^{131}I-radioiodine therapy for ablation of remnant thyroid tissue as well as to treat sites of micrometastatic disease not visualized by other imaging techniques or not amendable to surgical resection.[123] Diagnostic imaging is initially performed with ^{123}I-radioiodine to establish whether significant remnant tissue, iodine-avid lymph nodes, and metastatic disease are present in order to determine the appropriate therapeutic dose of ^{131}I-radioiodine. Higher doses are used for patients with extensive lymph-node involvement or

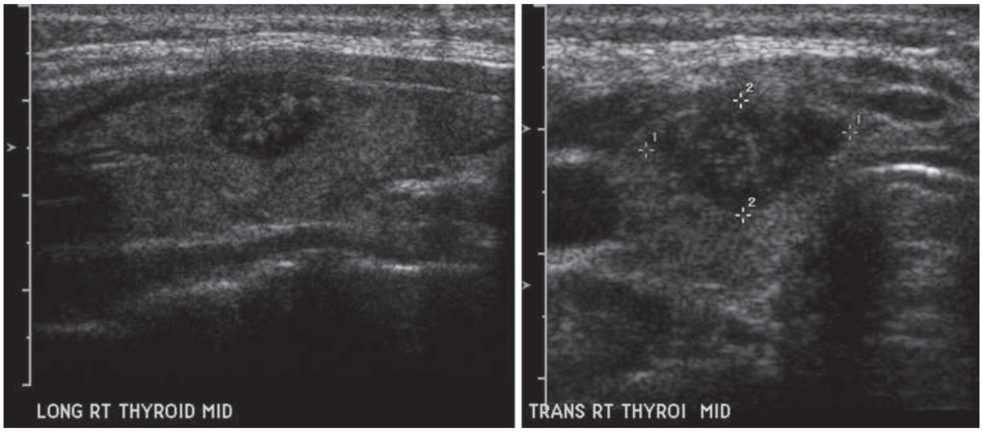

Figure 66-26 Follicular thyroid carcinoma. Palpable thyroid lesion with typical ultrasound imaging characteristics showing hypoechoic well-circumscribed mass. The mass is too small (≈1cm) to be accurately characterized by ^{123}I scintigraphy.

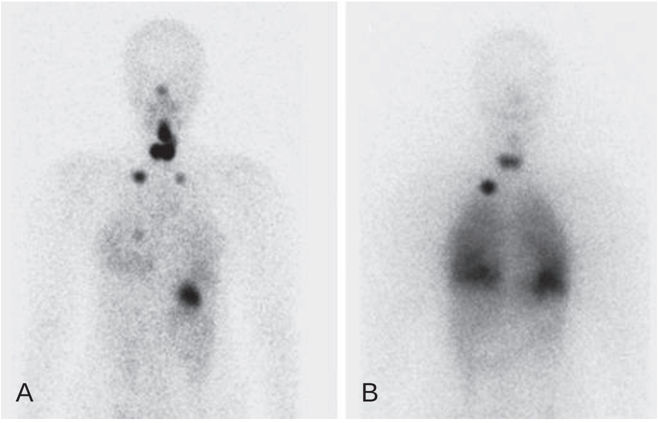

Figure 66-27 An 18-year-old patient with a history of stage-2 Hodgkin lymphoma treated with chemotherapy and radiation who developed a palpable thyroid nodule that was found to be papillary thyroid carcinoma. After thyroidectomy and lymph-node dissection, diagnostic imaging with ^{123}I radioiodine (**A**) shows intense uptake in the surgical bed, likely from remnant thyroid tissue, along with uptake in bilateral supraclavicular lymph nodes. Faint uptake is seen in the lungs. **B**, One week after therapy with ^{131}I radioiodine, remnant tissue and nodal uptake is reduced; however; intense pulmonary uptake is present, compatible with widespread pulmonary micrometastatic disease.

metastatic spread, as opposed to those with only remnant thyroid tissue in the surgical bed. As shown in Figure 66-27, the higher doses of ^{131}I used for therapy often allow sites of disease to be detected at the time of the post-therapy follow-up ^{131}I scintigraphy examination that were not apparent on the initial diagnostic ^{123}I scan.

Abnormalities of the parathyroid gland usually come to clinical attention during evaluation of hypercalcemic states. Functional parathyroid hyperplasia and parathyroid adenomas have a similar imaging appearance and can be very well characterized by ultrasound. There is usually no need for additional imaging by CT. Because of the variable anatomic locations of the parathyroid glands, it may be difficult to identify all potential sites of abnormality by conventional anatomic imaging techniques. ^{99m}Tc-Methoxyisobutylisonitrile (MIBI) scintigraphy is very sensitive and specific at showing focal accumulation of radiotracer in sites of functional parathyroid activity and can be used to identify sites of otherwise occult disease (Fig. 66-28).

Mediastinal Masses

The mediastinum is located in the center of the thorax, between the two thoracic cavities, the diaphragm, and thoracic inlet. It is conventional to divide the mediastinum into anterior, middle, and posterior mediastinal compartments based on their location as seen on the lateral chest radiograph. Although there are no distinct tissue planes that delineate these compartments, this system of classification is useful in characterizing diseases based on their tissue of origin.[124] Classifying mediastinal masses within a single mediastinal compartment helps narrow the differential diagnosis, calls attention to the potential effect of the mediastinal mass upon adjacent compartmental structures, and therefore commonly guides clinical decision making.[125]

Anterior Mediastinal Masses

The anterior mediastinum is defined as the prevascular space situated between the sternum and the heart, pericardium, and great vessels. The anterior mediastinum extends superiorly from the thoracic inlet to the level of the diaphragm. Organs located in the anterior mediastinum include thymus, thyroid, and parathyroid glands and prevascular-space lymphoid tissue. With respect to mediastinal mass formation, the thymus and anterior mediastinal lymph nodes are the two most important structures to be considered.

In infants, it is important to distinguish normal thymus from a mediastinal mass. The normal thymus typically has an undulating contour and on chest radiographs can be accurately identified based on subtle deformity by the adjacent anterior ribs' costal cartilages (Fig. 66-29). The normal thymus can be quite large and may extend posteriorly between the superior vena cava and aorta in the middle mediastinum or superiorly into the lower neck, making the distinction from neoplasm difficult.[125,126] In the appropriate clinical setting thymic hyperplasia may also be seen and is characterized by a homogeneously enlarged thymus. The thymus also may rapidly involute in response to physiologic stress, and this can also provide an indirect means of confirming its identity as normal thymus.

Lymphoma. Lymphoma is the most common tumor arising in the mediastinum and most commonly arises in either the anterior mediastinum or middle mediastinum. Both Hodgkin and non-Hodgkin lymphomas can present as mediastinal masses. The imaging features of Hodgkin lymphoma characteristically reveal a bulky anterior mediastinal mass with a nodular appearance. In addition, Hodgkin lymphoma is characterized by contiguous lymph-node spread, which may aid in the distinction

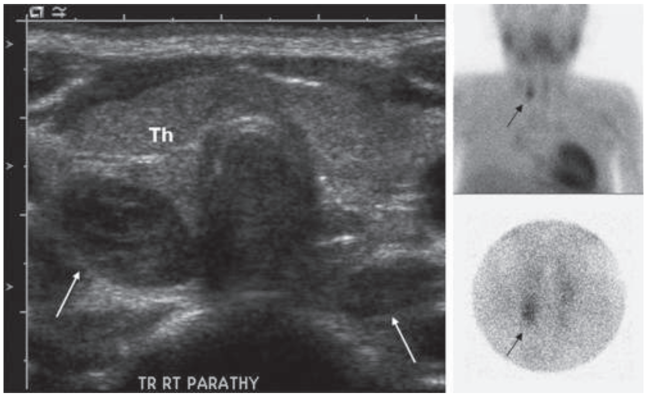

Figure 66-28 Parathyroid adenoma. Thyroid *(Th)* ultrasound showing a large hypoechoic mass on the right and a smaller lesion on the left *(arrows)* at the expected location of the parathyroid glands in an 11-year-old patient with end-stage renal disease and secondary hyperparathyroidism. The dominant mass on the *right* has corresponding increased uptake on ^{99m}Tc-MIBG scintigraphy, consistent with parathyroid adenoma. The lower levels of uptake in the smaller lesions are more in keeping with hyperplastic parathyroid tissue. ^{99m}Tc-MIBG is also effective at locating ectopically located parathyroid tissue (e.g., substernal) not visualized on thyroid ultrasound.

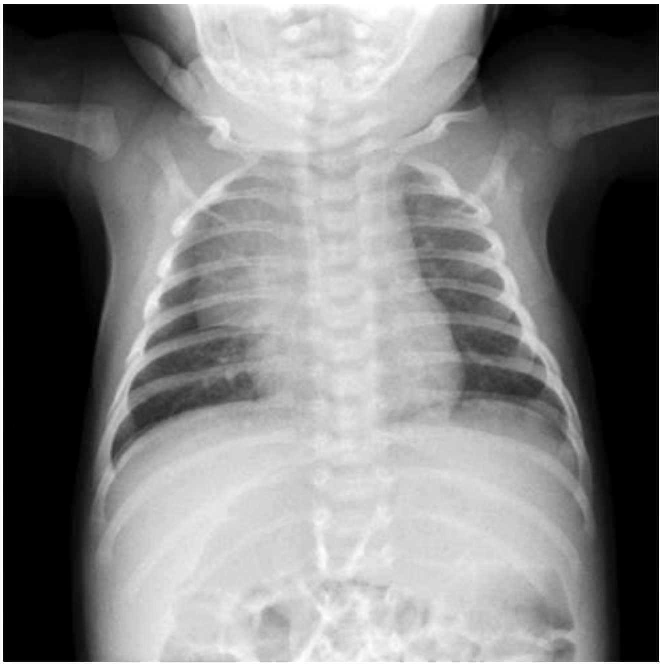

Figure 66-29 Anteroposterior chest radiograph of an infant shows prominent thymic shadow and undulating contour conforming to the adjacent ribs, findings all consistent with normal thymic tissue.

from other types of lymphoma. Approximately two thirds of pediatric patients with Hodgkin lymphoma show lymphadenopathy involving the mediastinum.[127] Non-Hodgkin lymphomas include lymphoblastic lymphoma and other subtypes.[127] Approximately one third of pediatric non-Hodgkin lymphomas have a mediastinal mass, and more than 50% of the lymphoblastic lymphomas have mediastinal involvement.[125] Although the distinction between some subtypes of non-Hodgkin and Hodgkin lymphoma may be difficult, acute T-lymphoblastic lymphomas often demonstrate a homogeneous infiltration and enlargement of the thymus gland with encasement/compression of the vessels (Fig. 66-30). All forms of lymphoma can result in significant tracheal compression/narrowing, vascular compression, and symptoms related to the superior mediastinal syndrome.[127,128] Pleural and pericardial effusions are seen in both non-Hodgkin and Hodgkin lymphomas of the mediastinum and are not a distinguishing feature. Bone-marrow involvement is seen in patients with either Hodgkin or non-Hodgkin lymphoma. Recent studies have shown that FDG-PET is a sensitive method for detecting bone-marrow involvement in children with Hodgkin lymphoma and can safely replace routine bone marrow biopsy for establishing the presence of marrow involvement.[129] Direct bone invasion by Hodgkin lymphoma is unusual; non-Hodgkin lymphomas often show more aggressive local involvement.

The imaging evaluation should always include a chest radiograph. In many instances this is the most important imaging study to guide the subsequent care of the patient. The presence of significant tracheal narrowing or tracheal displacement in the context of a large anterior mediastinal mass, particularly if accompanied by respiratory symptoms (see Figs. 66-2 and 66-30), should raise immediate concern for impending respiratory/cardiopulmonary compromise and prompt intensive care unit (ICU)–level monitoring.[128] Pneumomediastinum and pneumothorax may also be identified on these initial imaging studies (see Fig. 66-30). The placement of the patient in a recumbent position for CT scanning may further exacerbate the patient's already tenuous respiratory status, impair central venous return, and result in an acute cardiorespiratory event. In this setting it may be necessary to delay CT imaging, and the staging evaluation will have to be postponed until stabilization of the patient's clinical status.

In a stable patient, staging of anterior mediastinal lymphomas must include imaging of the neck to evaluate the Waldeyer ring of lymphoid tissue and should also include the abdomen and pelvis. Intravenous contrast should be used to provide an accurate assessment of the mediastinal vascular structures. Oral contrast should be provided to opacify the bowel and aid in the distinction from mesenteric lymphadenopathy.

MRI, particularly with faster scanning techniques, may be effective in evaluating mediastinal masses and staging lymphoma[130,131] but currently does not have an established role in the more acute stages of the evaluation. Gallium scintigraphy previously and currently FDG-PET imaging are recognized as standard of care in identifying sites of metabolically active lymphoma and in identifying sites of disease otherwise undetected by conventional imaging techniques (Fig. 66-31). FDG-PET scanning, in particular, has also been shown to play an important role in the posttreatment evaluation, helping to stratify patients into early responder and nonresponder groups to allow appropriate modulation of therapy based on treatment response (Fig. 66-32).[90,132,133-135]

After treatment, particularly of Hodgkin disease, it is common for the mediastinal mass to slowly regress and for residual inflammatory tissue to persist even months after therapy.[136,137] In contrast, lymphoblastotic lymphomas often respond quite rapidly to therapy with very little residual soft-tissue abnormality remaining in the anterior mediastinum, even after a relatively short duration of treatment (Fig. 66-33).[138] The use of FDG-PET for early response assessment in Hodgkin lymphoma is now considered standard of care, with images being simultaneously acquired and coregistered as fused PET-CT images to distinguish persistent metabolically active disease from residual posttreatment inflammatory tissue.[139-141] There is a large body of literature from both pediatric and adult patients showing that the presence of residual metabolically active disease after two cycles of chemotherapy is prognostically significant, presumably reflecting chemosensitive versus chemoresistant disease.[133,142,143,144-146] Patients with residual CT abnormalities that are FDG-avid have a worse overall outcome as compared with patients whose scans are FDG-negative, which has led to a paradigm shift in Hodgkin lymphoma therapy such that patients in whom early response assessment shows no metabolically active disease would be eligible for reduced chemotherapy and radiation in an effort to reduce treatment-related complications.[144,147] Whether this approach will maintain the good outcomes (>90%

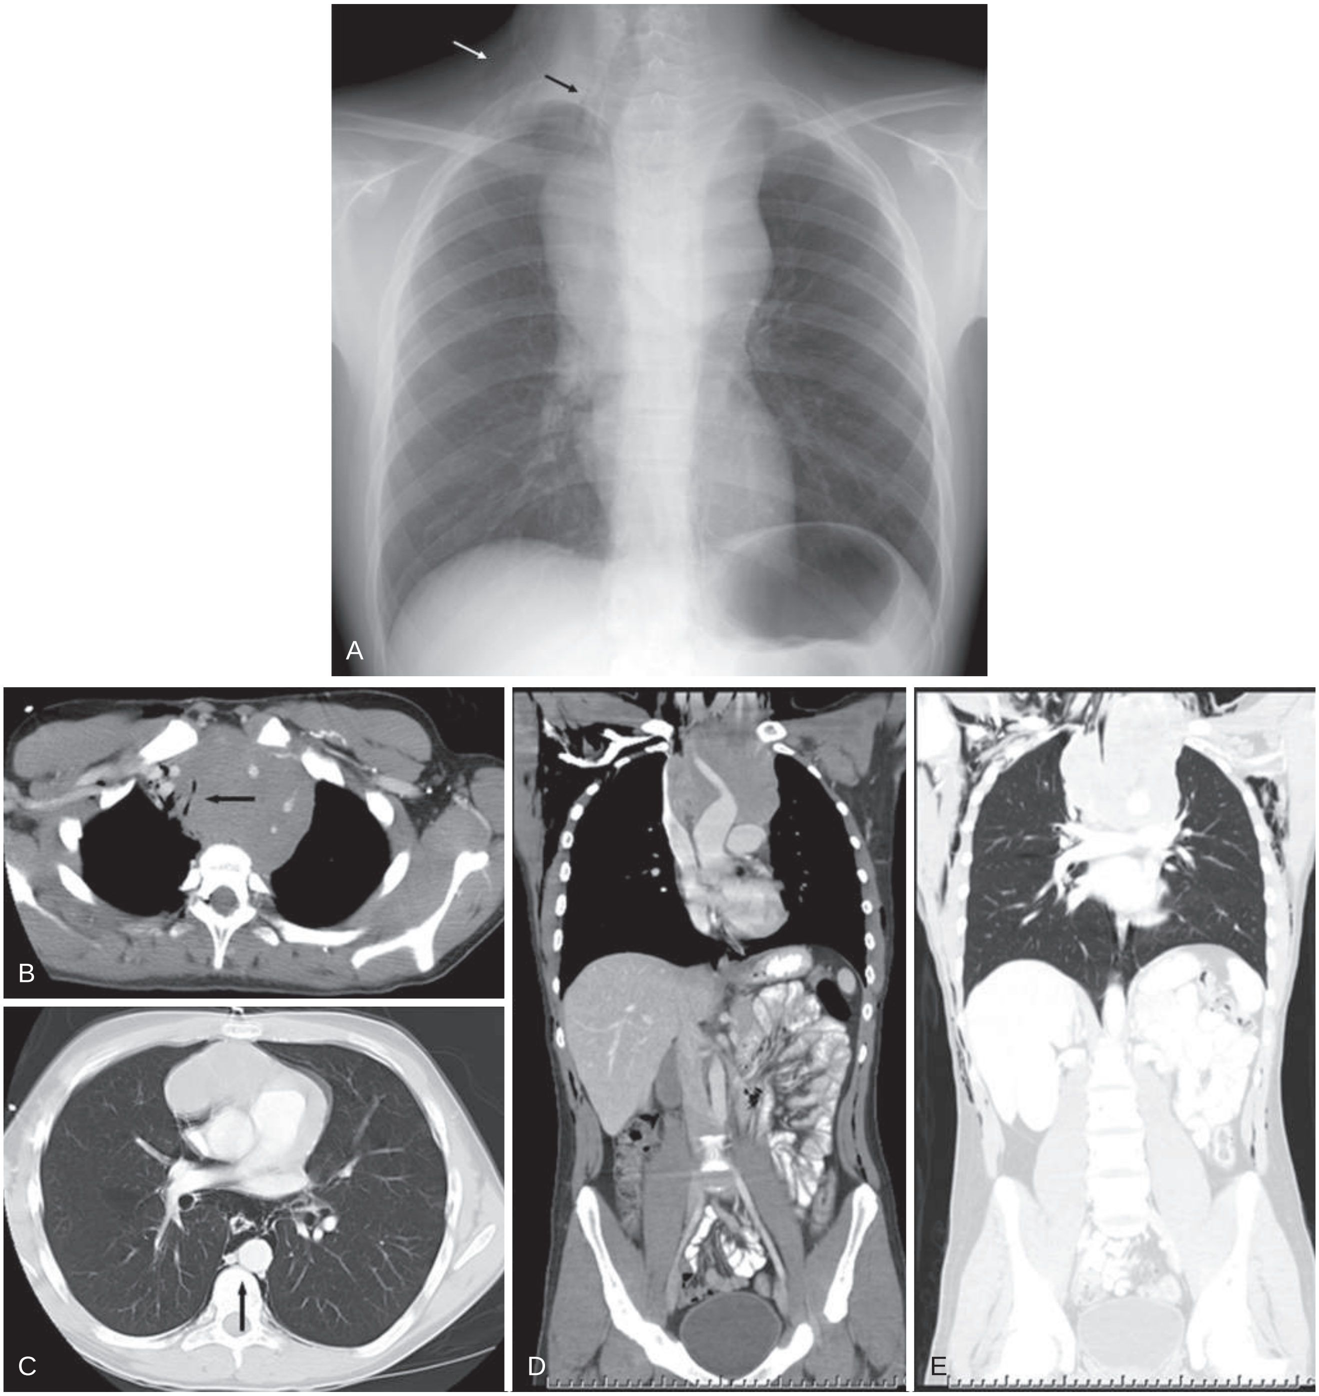

Figure 66-30 **A**, Chest x-ray showing marked tracheal deviation, pneumomediastinum, and subcutaneous emphysema along the right neck in a child with lymphoblastic lymphoma, emphasizing the severity of airway obstruction and potential for respiratory compromise *(arrows)*. **B-E**, CT shows large anterior mediastinal mass with mediastinal air around the heart, pulmonary vessels, aorta, and esophagus (**C**). The trachea is markedly narrowed *(arrow)*, likely the cause of the pneumomediastinum. Subcutaneous air is also evident in the anterior chest wall. Five days later the findings had progressed considerably (**C** and **D**).

overall survival) typically seen in Hodgkin lymphoma remains to be seen.[148,149] There is currently no convincing data showing the prognostic value of FDG-PET imaging in non-Hodgkin lymphoma.[150]

Germ-Cell Tumor. Mediastinal germ-cell tumors are primarily located in the anterior mediastinum near the thymus gland and make up about 10% to 20% of all childhood mediastinal tumors. Germ-cell tumors are second only to lymphoma as the cause of a thymic/anterior mediastinal mass. When they present as predominately solid masses, they may be difficult to distinguish from lymphoma. Histologically, mature teratomas are the most common germ-cell tumor arising in the

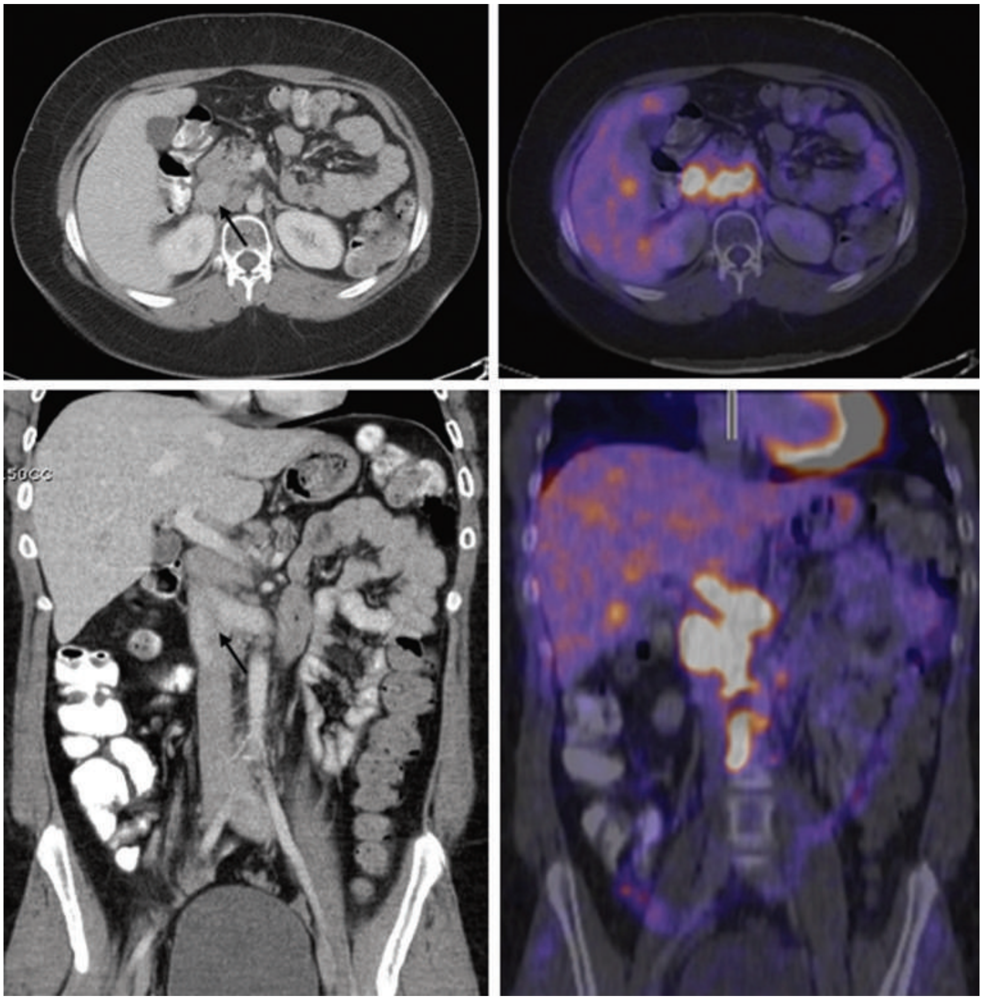

Figure 66-31 FDG-PET and image fusion delineate equivocal areas of abnormality on CT *(arrows)*, identifying foci of disease recurrence in a patient with Hodgkin lymphoma.

mediastinum.[151] At diagnosis, calcification of lymphoma is unusual, and the calcifications that are often present in teratoma may suggest the diagnosis. Germ-cell tumors are often asymptomatic and may be identified incidentally as mediastinal masses on chest radiographs obtained for other indications.[152] When symptoms are present, they are usually the result of compression of the tracheobronchial tree.

Either CT or MRI scanning are effective at further characterizing these masses. The presence of fluid attenuation, mixed attenuation fluids and gelatinous material, fat, and calcification all should suggest the diagnosis of mediastinal germ-cell tumor (Fig. 66-34). Ten percent to 20% of all mediastinal germ-cell tumors are malignant and present with signs of local invasion into the pleura or pericardium. Malignant tumors include seminomatous and nonseminomatous histologic subtypes. Seminomas tend to be noncalcified, bulky solid masses that either remain localized or spread to local lymph nodes, whereas other malignant germ-cell tumors display greater heterogeneity with cystic and solid elements and more aggressive, locally invasive features.[153] Germ-cell tumors may rupture into the pleural or pericardial spaces, the lung parenchyma, or the tracheobronchial tree. Imaging evaluation should be directed at determining the extent of rupture and sites of tissue involvement. Chemical pneumonitis can result from parenchymal rupture, and expectoration of blood, hair, and sebaceous material can result from rupture into the airways.[154]

Thymic Masses

Thymoma. Thymoma is rare in children, accounting for less than 4% of pediatric mediastinal tumors.[125] As with adults, thymoma may present with symptoms related to associated autoimmune disorders, including myasthenia gravis, diabetes, and Hashimoto thyroiditis. Thymomas are typically solid, lobulated masses arising in or around the thymus (Fig. 66-35). The imaging evaluation should be directed at assessing for aggressive features such as invasion into adjacent pericardial or pleural structures. MRI and contrast-enhanced CT reveal a heterogeneously enhanced low-density mass that is isointense on T1-weighted images and mildly T2 hyperintense relative to muscle.[125] Both CT and MRI are excellent in

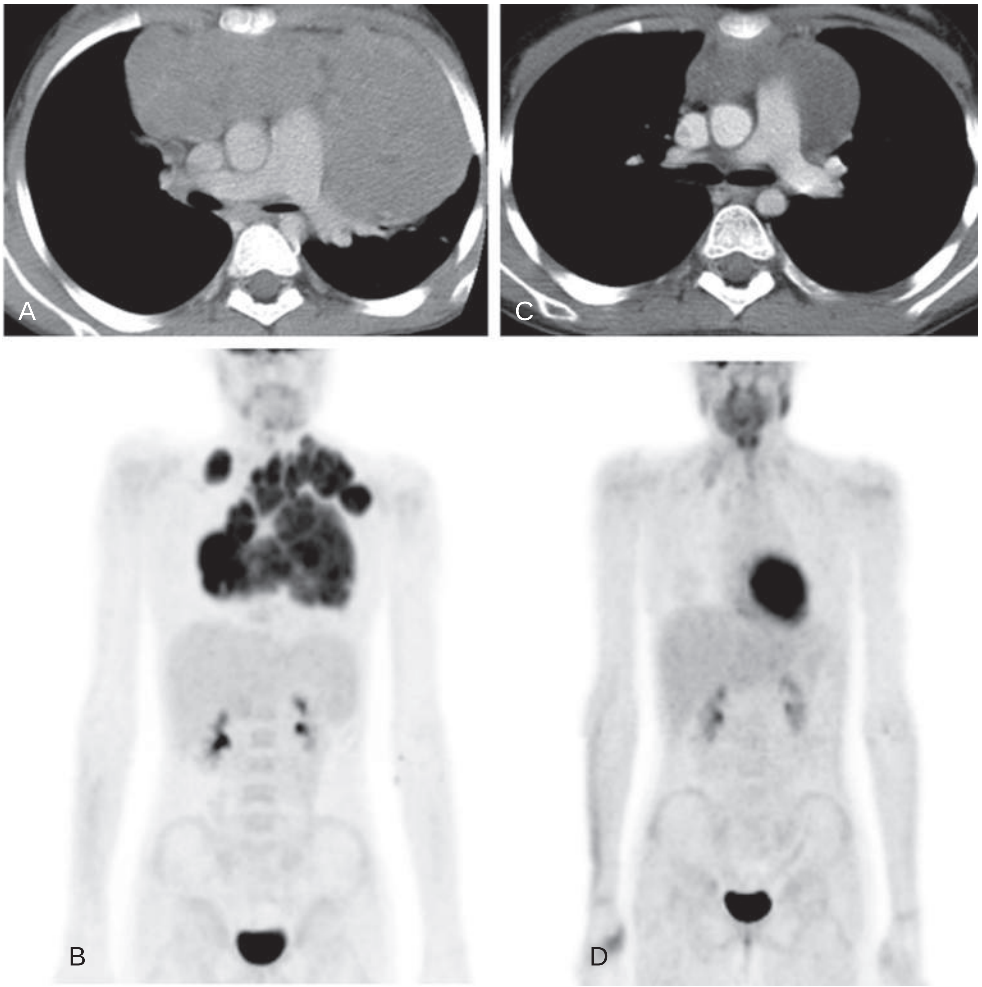

Figure 66-32 Hodgkin Lymphoma CT and FDG-PET obtained at diagnosis (**A** and **B**) and after 2 cycles of chemotherapy (**C** and **D**) show excellent functional and anatomic response to therapy. Residual mediastinal mass on CT with no residual FDG uptake emphasizes the potential importance of functional imaging in response assessment.

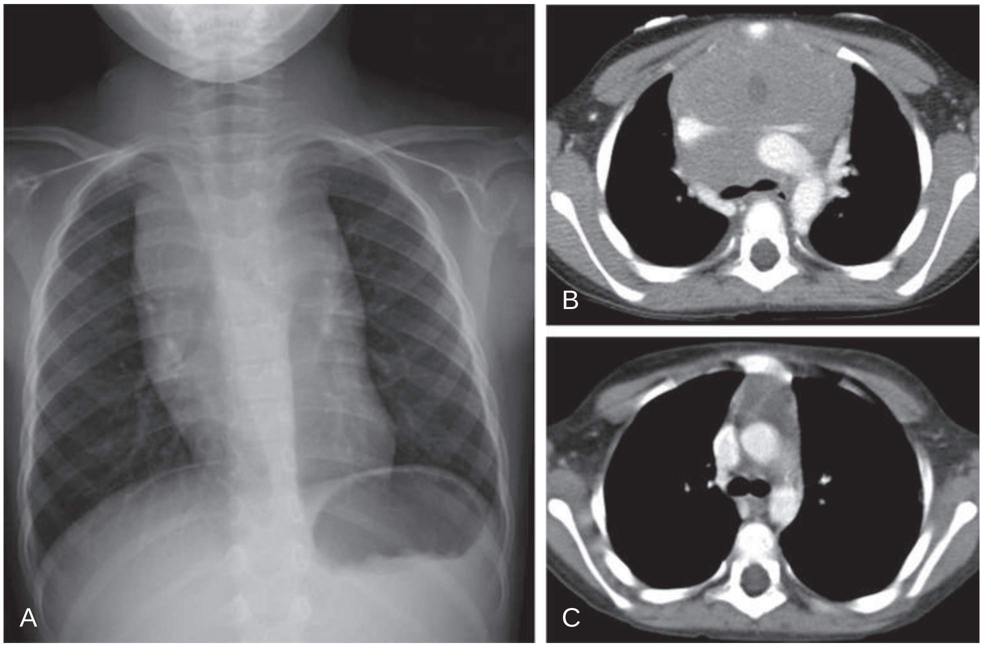

Figure 66-33 A 4-year-old child with T-cell ALL and a large mediastinal mass with airway and vascular compression seen by CXR (**A**) and CT (**B**), showing near complete resolution of the mass after just 2 weeks of therapy (**C**).

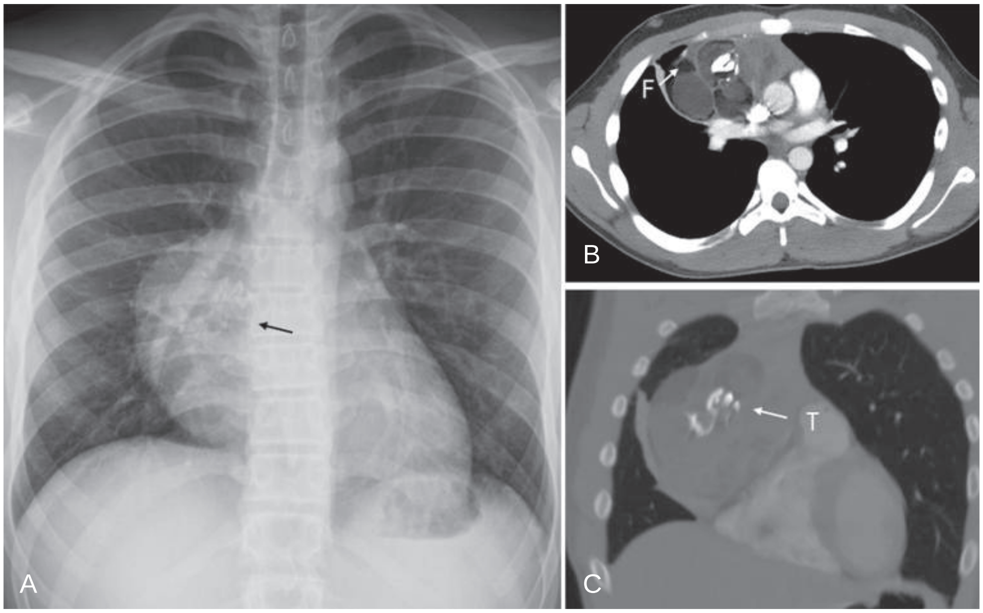

Figure 66-34 A 15-year-old boy with mediastinal mass seen incidentally on a chest x-ray obtained for pain after a football injury (**A**). Subsequent CT (**B** and **C**) shows fat *(F)* and adjacent solid elements in addition to calcification, in this case taking the form of tooth *(T)*, characteristic of germ cell tumor, in this case mature teratoma.

delineating the relationship of these masses to the adjacent vascular structures (see Fig. 66-35). Nodular pleural or pericardial thickening should raise concern for invasive thymoma. Because complete surgical resection is the most effective treatment for ensuring long-term survival for patients with thymoma, postsurgical radiation therapy may be considered when invasive features are present.[155]

Thymolipomas. Thymolipoma, in contrast to thymoma, is relatively more common, making up about 3% to 9% of pediatric thymic tumors.[156] These benign tumors are most often seen in older children, but they may present in infancy. These heterogeneous masses may contain calcification and cystic areas, making distinction from germ-cell tumors challenging. A predominantly fatty mass should, however, suggest the diagnosis of thymolipoma (Fig. 66-36). The fat characterization can be sensitively and specifically evaluated by MRI, showing a high signal-intensity mass on T1-weighted imaging with loss of signal on fat-suppressed images.[156] A low-attenuation mass with negative Hounsfield-unit density on either unenhanced or contrast-enhanced CT can also suggests the presence of a fat-containing mass (see Fig. 66-36).

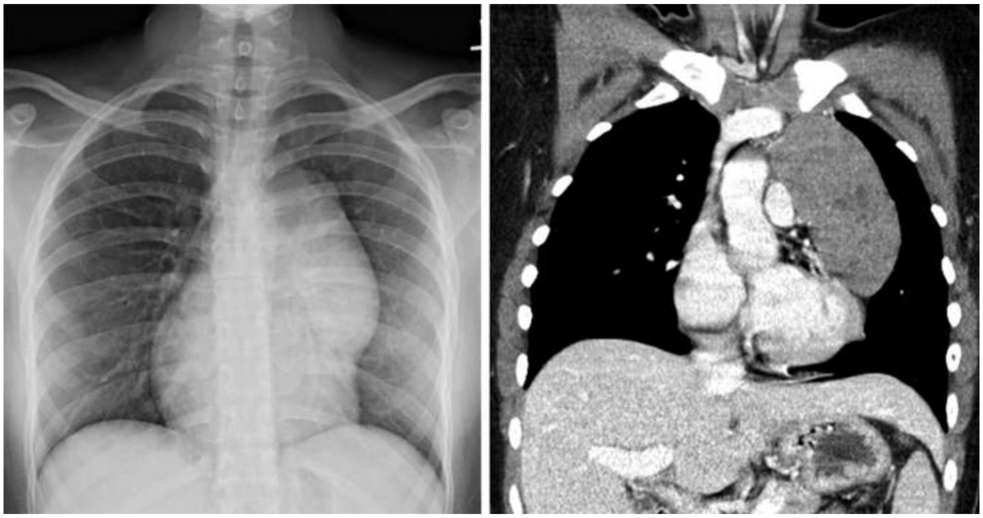

Figure 66-35 A 15-year-old girl with a 2-week history of chest pain. Chest x-ray and CT show a large, lobular, heterogeneous anterior mediastinal mass abutting the great vessels, with a poorly defined plane between the mass and normal mediastinal structures. Biopsy revealed thymoma, and the patient underwent complete resection.

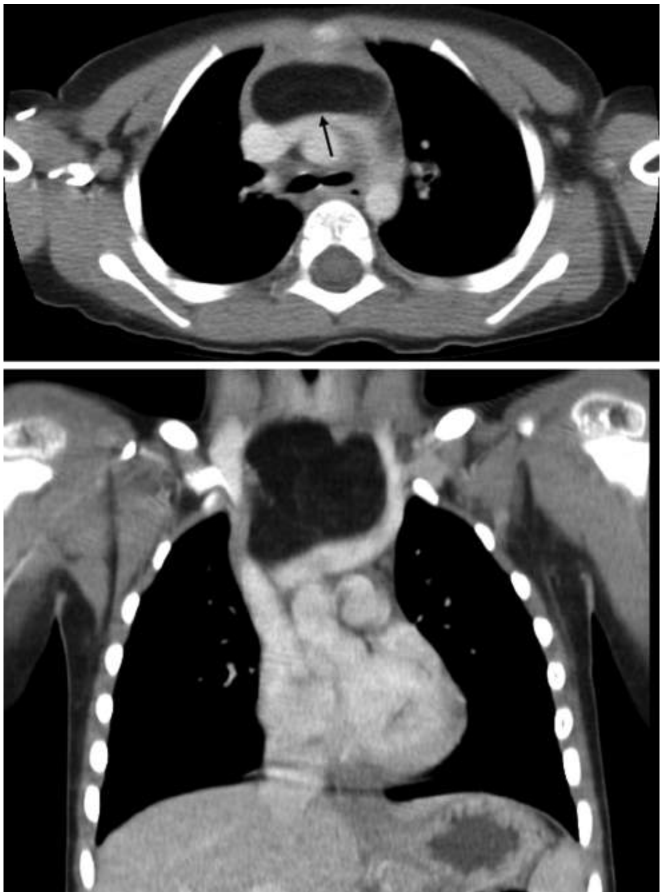

Figure 66-36 Thymolipoma in a child with an incidentally detected mediastinal mass on chest x-ray. Note the fat-density mass *(arrow)* located within the thymus.

Middle Mediastinum

Tracheobronchial Tree Masses. The middle mediastinum is defined as the vascular space including the pericardium/heart, the great vessels, and trachea/proximal bronchi and associated lymph nodes. Although the most common middle mediastinal mass is lymphoma, lymphoma is rarely isolated to the middle mediastinum and usually occurs in conjunction with a large anterior mediastinal mass. The most common masses isolated to the middle mediastinum are benign bronchopulmonary foregut malformations, including bronchopulmonary sequestration, congenital cystic adenomatoid malformation (C-CAM), and foregut/bronchogenic cysts.[124] These benign masses are not discussed further in this section except to emphasize that the distinction between cystic adenomatoid malformation and pleuropulmonary blastoma cannot be made on the basis of imaging alone (Fig. 66-37). Surgical resection and histopathologic evaluation is required to distinguish the benign C-CAM from its neoplastic counterpart.

Masses of the endobronchial tree are also exceedingly rare in children. The most common endobronchial neoplasm in children is the bronchial carcinoid tumor, making up about 50% of all bronchial neoplasms.[157] Although these tumors may secrete neuroendocrine peptides, the classic carcinoid syndrome is relatively unusual in children with bronchial carcinoids, and these patients are more likely to have presenting respiratory symptoms such as hemoptysis or lobar atelectasis/partial collapse caused by the obstructing endobronchial lesion (Fig. 66-38). These lesions are commonly hilar in location and may be very difficult to identify on chest radiographs. The presence of a persistent area of segmental or lobar collapse that does not resolve after appropriate therapy should prompt further investigation by CT scanning to directly assess the airways. Multidetector-row CT scans can provide exquisite 3D reformations of the airways and allow accurate detection of endobronchial abnormalities. Chest CT of patients with suspected endobronchial carcinoid tumor may be performed without intravenous contrast for the purpose of identifying the endobronchial lesion; however, contrast infusion typically shows prominent enhancement of these highly vascular lesions. There may be intraluminal, mural, and extraluminal components of these lesions, and the extraluminal extent of the lesion may exceed its intraluminal component.[158] Although the presence of calcification in an endobronchial mass should suggest the diagnosis of a carcinoid tumor, calcification is still relatively rare in childhood bronchial carcinoid tumors. Surgical resection is usually curative, and although the extent of local invasion around the primary lesion is variable, metastatic disease is relative rare (5% to 20%). Uptake of the neuroendocrine-specific radiotracer ^{111}I-octreotide provides highly specific scintigraphic imaging confirmation of the diagnosis (see Fig. 66-38, *C* and *D*) and may aid in identifying occult sites of metastatic disease. FDG-PET imaging of metabolically active carcinoid tumors has also been performed and, although not specific for neuroendocrine tumors, may prove to be a sensitive means of identifying occult metastases.

Mucoepidermoid carcinoma is the second most common primary bronchial neoplasm. These patients also have primarily respiratory presenting symptoms related to airway obstruction. Because primary airway neoplasia in children is rare and commonly characterized by nonspecific clinical symptoms, the diagnosis is often delayed and difficult to distinguish from infectious processes such as pneumonia. The most common finding on plain chest radiographs in patients with mucoepidermoid carcinoma is a central mass or nodule.[159,160] These tumors range from low to high grade, with high-grade neoplasms tending to invade the adjacent pulmonary parenchyma. As with carcinoid tumors, multidetector-row CT with multiplanar and 3D reformats can be used to accurately identify an airway abnormality.[160,161] However, in contrast to carcinoid tumors, mucoepidermoid carcinoma is relatively hypovascular and shows minimal enhancement. Recent studies have also suggested that FDG-PET imaging may be used to advantage in staging patients with mucoepidermoid carcinoma,[160] with intense FDG uptake visualized (Fig. 66-39).

Tumors of the heart and pericardium are very rare in children. The majority of these are rhabdomyomas arising from the neoplastic transformation of cardiac myocytes. There is a well-known association between cardiac rhabdomyoma and tuberous sclerosis (Fig. 66-40), with

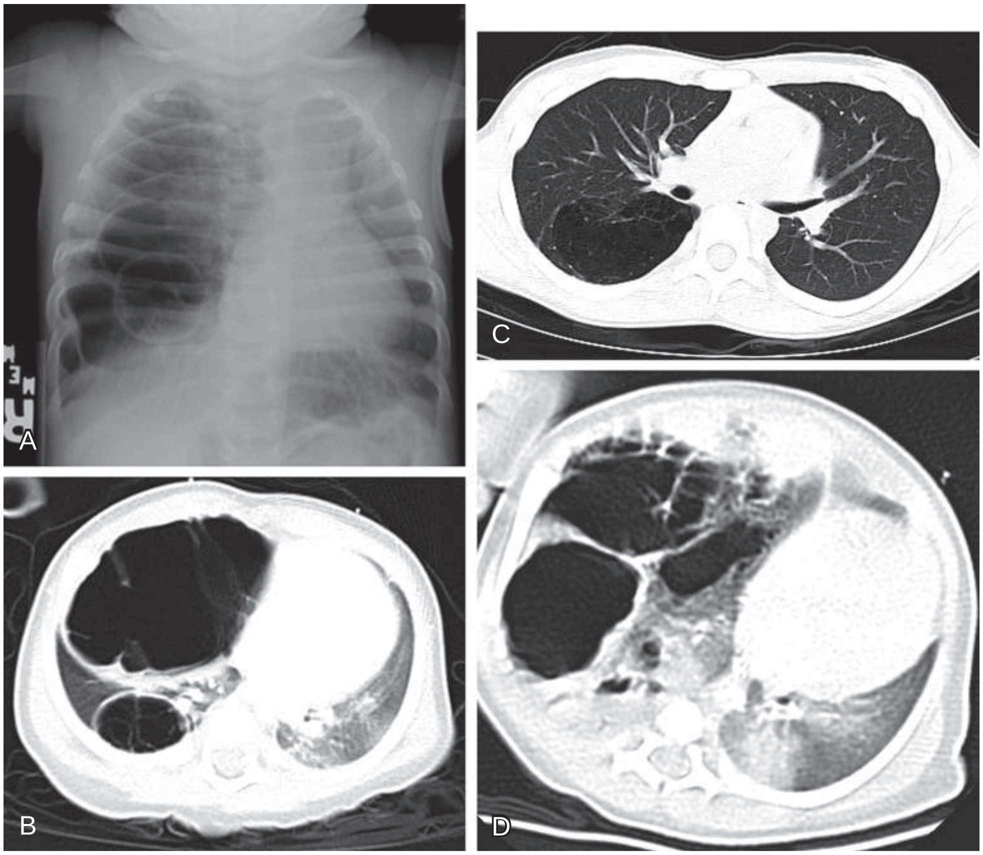

Figure 66-37 Pleuropulmonary blastoma (**A** and **B**). Note the difficulty in distinguishing this malignancy from C-CAM (**C** and **D**).

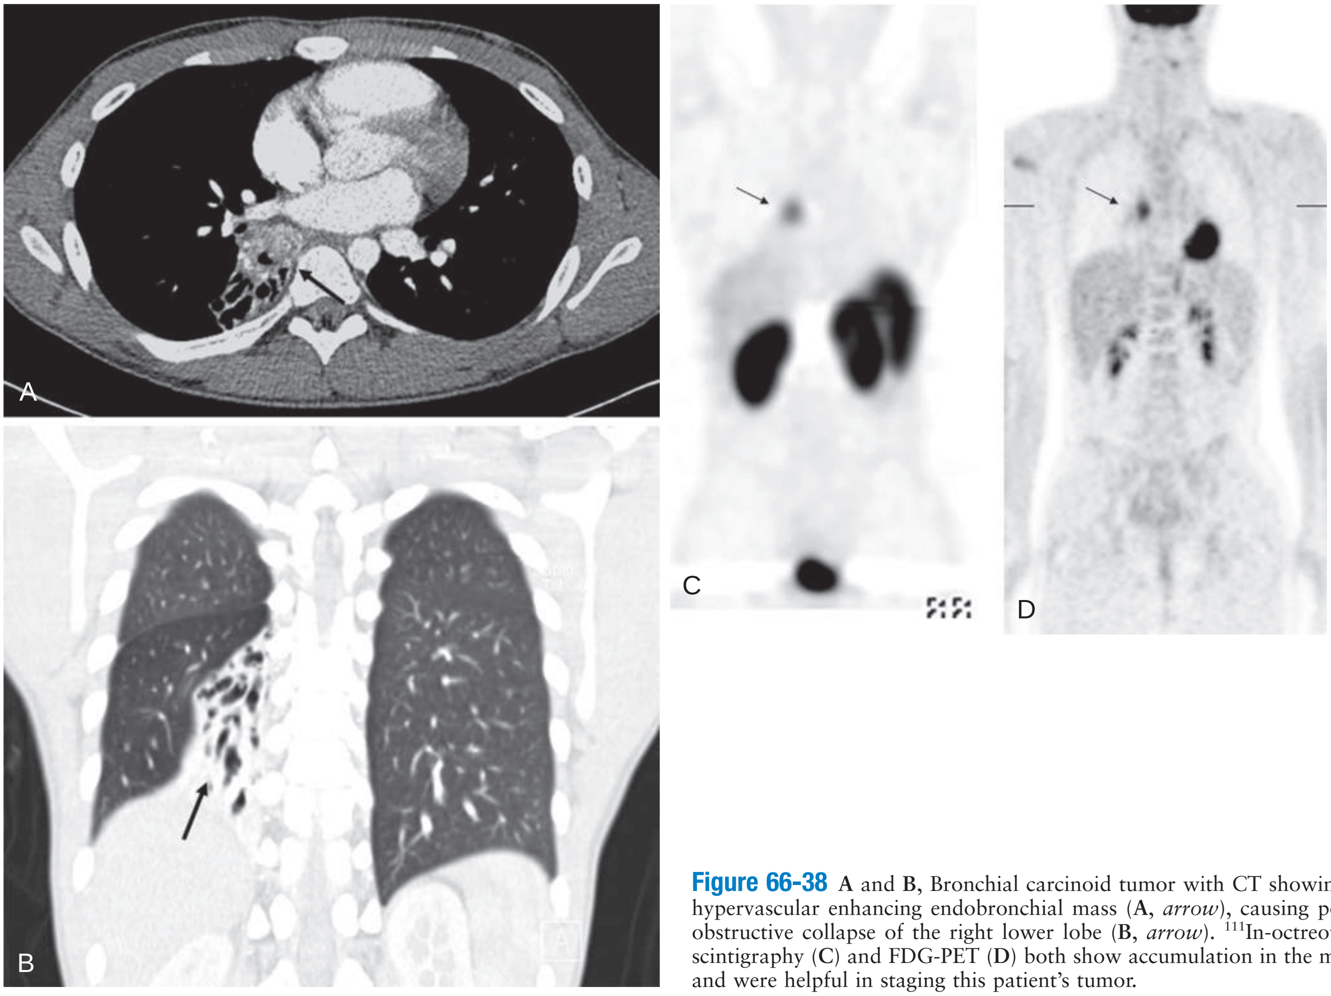

Figure 66-38 **A** and **B**, Bronchial carcinoid tumor with CT showing a hypervascular enhancing endobronchial mass (**A**, *arrow*), causing post-obstructive collapse of the right lower lobe (**B**, *arrow*). ^{111}In-octreotide scintigraphy (**C**) and FDG-PET (**D**) both show accumulation in the mass and were helpful in staging this patient's tumor.

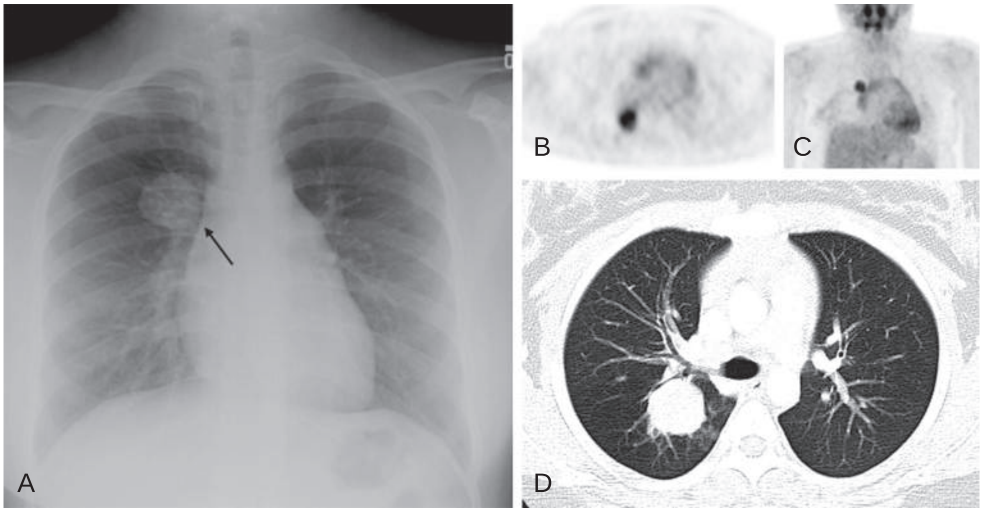

Figure 66-39 Mucoepidermoid carcinoma. Chest x-ray for symptoms of nonspecific upper respiratory infection showed right upper lobe mass (**A**). CT shows posterior segment upper lobe mass compressing the posterior segment bronchus with mild associated air-trapping (**D**). FDG-PET (**B** and **C**) showed intense uptake and was helpful for staging.

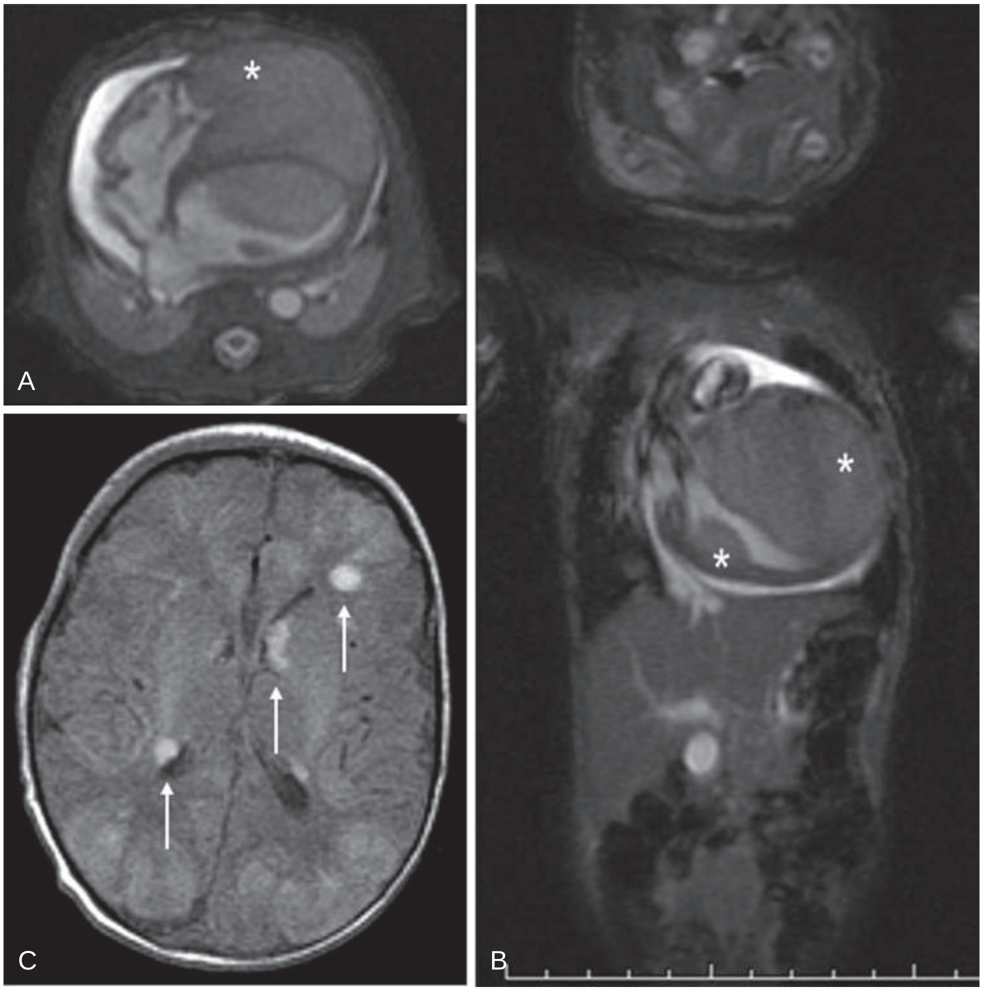

Figure 66-40 Cardiac rhabdomyoma. A 5-day-old infant with a large chest mass and tuberous sclerosis. **A**, Cardiac MRI showed multiple rhabdomyomas *(asterisks)*, the largest obliterating the right ventricle. **B**, Multiple smaller tumors are in the left ventricle, both adherent to the septum and along the free wall. **C**, Brain MRI shows multiple subependymal and cortical tubers *(arrows)*.

approximately half of the patients with this diagnosis having rhabdomyomas.[162] Indeed the presence of a rhabdomyoma should prompt further evaluation, because rhabdomyomas may be the initial presenting sign of tuberous sclerosis.

When symptoms are present, they are usually the result of tumor protruding into the cardiac lumen, resulting in outflow obstruction and congestive failure. Echocardiography is usually sufficient to suggest the diagnosis; however CT scanning and cardiac MRI are superior at defining the extent and attachments of these cardiac tumors and may be indicated for surgical planning. Cardiac fibromas and myxomas are much less common. Indeed it is more common to see secondary extension into the heart by other primary pediatric neoplasms such as neuroblastoma and Wilms tumor, both of which have a propensity to extend into the heart via the inferior vena cava (IVC); hepatoblastoma, which may show direct intracardiac extension (Fig. 66-41); and mediastinal lymphoma, which may result in chest wall/pericardial involvement. Contrast-enhanced CT scanning usually allows an accurate delineation of sites of local extension in the thorax. Either abdominal ultrasound, multiphase contrast-enhanced CT, or MRI can be used to demonstrate intravascular/intracardiac extension from primary abdominal malignancies.

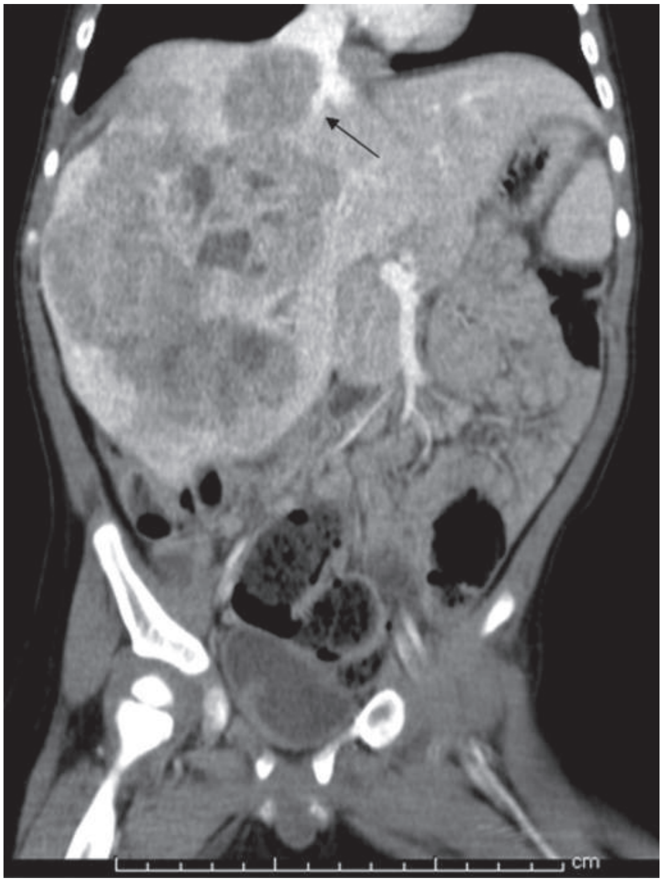

Figure 66-41 Coronal contrast-enhanced CT showing direct extension into the IVC in a 15-month-old patient with hepatoblastoma.

Posterior Mediastinal Masses

The posterior mediastinum is defined dorsally by the chest wall/vertebral column, ventrally by the pericardium and posterior wall of the great vessels, superiorly by the thoracic inlet, and inferiorly by the diaphragm. The primary components of the posterior mediastinum are the paravertebral sympathetic ganglia, azygos and hemiazygos veins, descending thoracic aorta, esophagus, and lymph nodes. The majority of the posterior mediastinal masses in children are neurogenic in origin[125,163] and include ganglion-cell tumors, nerve-sheath tumors, and other nervous-tissue neoplasms such as paragangliomas. Ganglion-cell tumors arise from sympathetic chain ganglia and range from well-differentiated and benign ganglioneuromas to malignant neuroblastomas. Ganglioneuroblastomas contain elements of both benign and malignant tissue types. The distinction between these different histologic subtypes cannot be made reliably based on imaging features, although age at presentation is important in narrowing the differential diagnosis. Neuroblastoma, the most common non-CNS solid tumor in children, typically occurs in young children with a median age at presentation of younger than 2 years and more than 95% of cases occurring by the age of 10 years. In contrast, the median age at presentation of ganglioneuroblastoma is approximately 5.5 years, whereas mature ganglioneuromas occur in later childhood/early adolescence, typically after the age of 10.[164] Whereas the majority of neuroblastomas occur in or around the adrenal gland, approximately 15% arise in the posterior mediastinum.[165]

It is important to emphasize that these lesions may be present in a child who is otherwise asymptomatic, and a thorough inspection of the chest radiograph using multiple windows and levels is necessary to identify small foci of disease. This is of particular importance, as shown in Figure 66-42, because a localized low-stage favorable histology neuroblastoma identified in a child under the age of 1 year may make the difference between being treated on low-risk protocols with higher likelihood of overall and disease-free survival versus more advanced stages of disease, when the patient's risk of relapse and treatment failure increases.[166] Primary intraabdominal neurogenic tumors may also have a significant posterior mediastinal extent and often have an associated posterior mediastinal/paravertebral component near the thoracic inlet (Virchow node). For this reason, it may be prudent to include imaging of the chest, in addition to the abdomen and pelvis, in the staging evaluation of patients with suspected neuroblastoma.

Radiographically, ganglion-cell tumors appear as paraspinal soft-tissue masses. Calcifications may be present. The presence of chest-wall invasion or destructive bony changes are more commonly seen with neuroblastoma, although benign ganglioneuromas can produce a considerable neural foraminal widening. As with primary adrenal neuroblastomas, staging should include ^{123}I-MIBG scintigraphy to assess for other sites of disease, including marrow involvement. ^{99m}Tc-MDP bone scintigraphy is also commonly performed to identify sites of

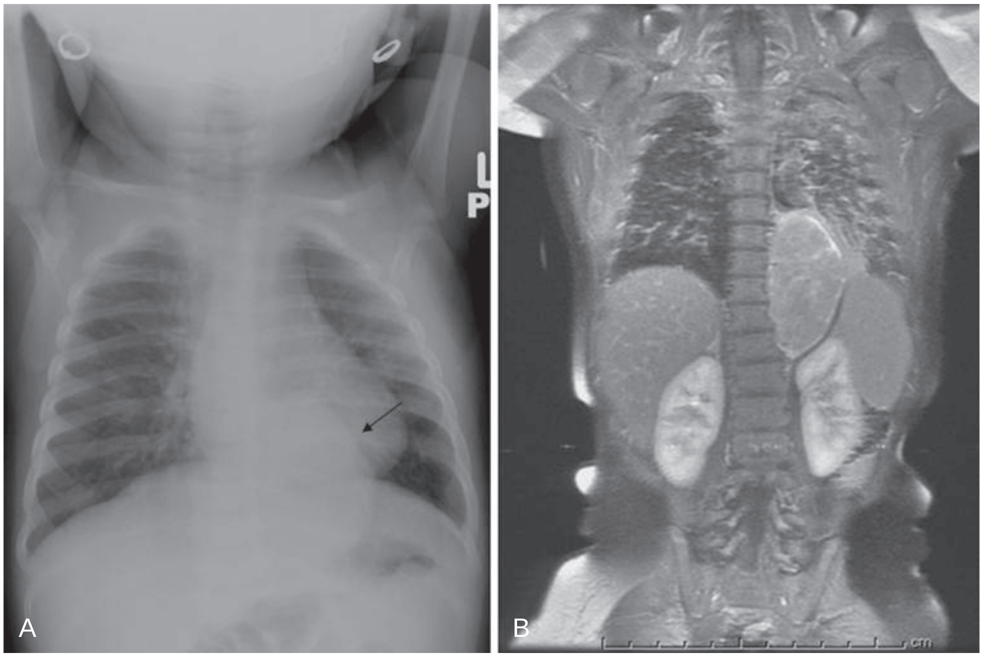

Figure 66-42 Posterior mediastinal neuroblastoma in a 5-month-old infant who showed symptoms of an upper respiratory infection. A posterior mediastinal mass was identified by chest x-ray (**A**) and MRI (**B**). Surgery revealed neuroblastoma. Subsequent staging confirmed low-stage disease.

cortical bone involvement,[91] although recent data suggests that bone scintigraphy rarely affects that clinical stage of the patient. The presence of a paraspinal mass can usually be adequately assessed by CT scanning, particularly with sagittal and coronal reconstructions. However, the extent of intraspinal extension is better depicted by MRI (Fig. 66-43).[125] MRI also provides a more accurate assessment of chest-wall involvement, nerve-root compression, and impingement upon the spinal cord. MRI of ganglion-cell tumors typically reveals a low signal-intensity lesion on T1-weighted images and intermediate to high signal intensity on T2-weighted and fast spin echo inversion recovery (FSEIR) images, with variable patterns of enhancement. Bone-marrow metastases are well demonstrated by MRI, with replacement of normal bone-marrow signal by areas of low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. Indeed, several studies have suggested that MRI may be sufficient to identify sites of bone-marrow involvement in neuroblastoma, although is has not yet become common in clinical practice to rely on the MRI findings of bone-marrow involvement for staging of the patient.[167,168] The use of FDG-PET in neuroblastoma has received attention as an alternative to conventional imaging techniques.[91] However, a number of studies have shown variable patterns of FDG avidity in neuroblastoma, and FDG-PET has not yet been shown to offer a clear advantage over MIBG scintigraphy in either the staging or response assessment of patients with thoracic neuroblastoma.[169-171]

Nerve-sheath tumors, including schwannomas and neurofibromas may be similar in appearance to mature ganglion cell tumors, presenting as relatively sharply marginated, lobulated paraspinal masses. The presence of rib erosions and neural foraminal widening is commonly seen with nerve-sheath tumors, although intraspinal extension is less common. Paraspinal paragangliomas are catecholamine-secreting tumors arising from extra-adrenal chromaffin cells present in sympathetic chain ganglia and occur much less often than either primary ganglion-cell or nerve-sheath neoplasms. Distinguishing between these tissue types is difficult on the basis of imaging, and surgical resection is the mainstay of therapy. Local recurrence can occur, however, and close imaging follow-up is necessary in these patients.

Chest-Wall/Pleural-Based Neoplasms

Most of these tumors are of mesenchymal origin and are primary neoplasms arising from the chest wall. They are relatively rare in infants and children, with a reported incidence of approximately 2% of all pediatric tumors.[172] The most common chest-wall neoplasms are the Ewing sarcoma family of tumors and primitive neuroectodermal tumors (PNETs), collectively known as Askin tumors. These tumors have a peak incidence between 10 and 15 years of age and are more common in males. Because of their origin within the chest wall and propensity to invade the adjacent bone, symptoms are commonly of a palpable mass or pain secondary to local extension. Chest radiography should be the first imaging study in the evaluation of these patients and is usually accurate at depicting sites of bone destruction, pleural effusion, and pleural thickening. CT and/or MRI are almost always performed to better delineate the extent of local disease. CT scanning of the chest is essential to assess for the presence of pulmonary metastatic disease (Fig. 66-44). For paravertebral and intercostal masses, MRI may also be necessary to identify and accurately delineate the extent of intraspinal involvement. FDG uptake is usually seen with these

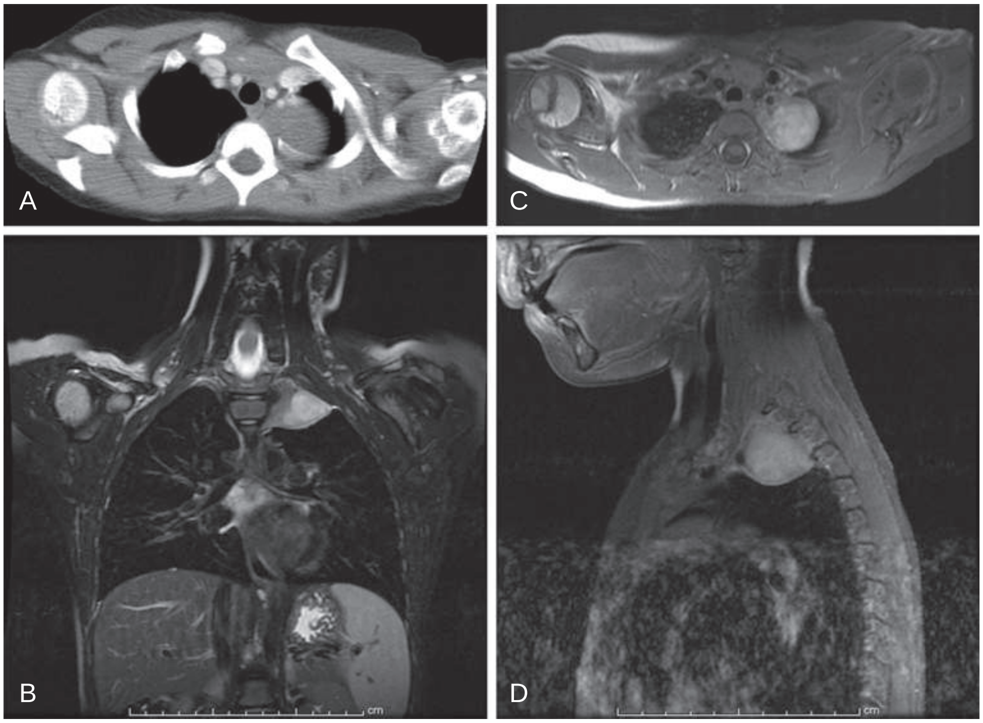

Figure 66-43 A 7-year-old child with a cough. Chest x-ray showed left upper lobe opacity. **A**, CT shows paraspinal mass. **B**-**D**, MRI shows the mass to much better advantage. Cor FSEIR and post–Gd-enhanced images (**C** and **D**) show the mass abutting the neural foramina and left subclavian vessels. MIBG scanning showed barely detectable uptake in the mature ganglioneuroma *(not shown)*.

tumors,[173] and as with Ewing sarcomas of the appendicular skeleton, FDG-PET imaging should be considered both for identifying sites of occult disease that would otherwise go undetected and for monitoring responses to therapy when complete surgical resection cannot be achieved.[174-176]

Wide excision of the primary tumor is critical for local disease control, with variable response to radiation therapy and chemotherapy.[177,178] These chest-wall neoplasms are extremely malignant and can be quite destructive, demonstrating extensive invasion into the airways, local vascular structures, and the lung parenchyma. There is a high rate of both metastatic spread and of local recurrence, and cure requires intensive therapy to control both distant and local disease. The presence of disseminated disease invariably results in a poor long-term outcome in patients with these aggressive poorly responsive tumors.[178]

Rhabdomyosarcoma is the most common soft-tissue sarcoma of childhood and is the second most common

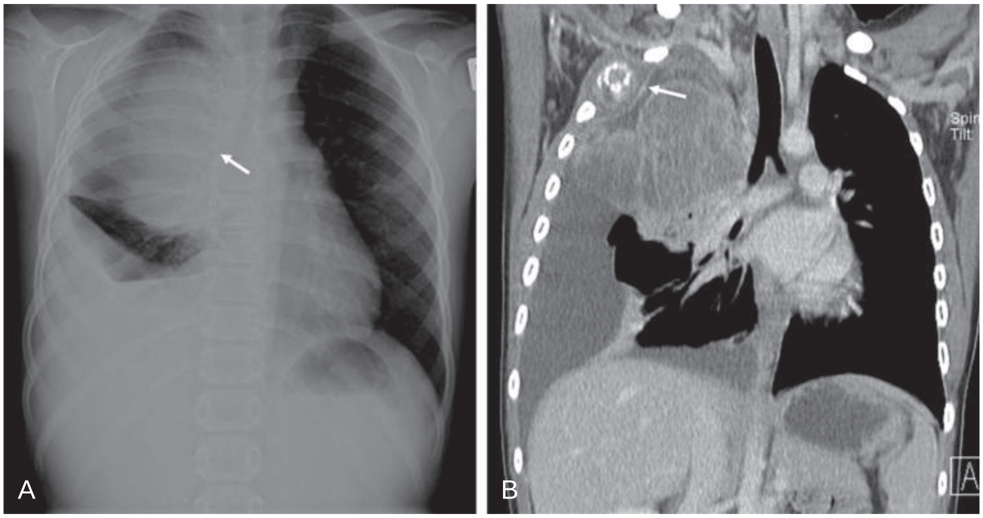

Figure 66-44 Ewing sarcoma of the chest wall in a 6-year-old patient with fever and a chest-wall mass detected by chest x-ray. **A**, Chest x-ray shows pleural effusion, central chest-wall mass *(arrow)*, and partial lung collapse. **B**, Contrast enhanced CT shows a large, locally invasive chest wall mass with pleural involvement and rib destruction *(arrow)*.

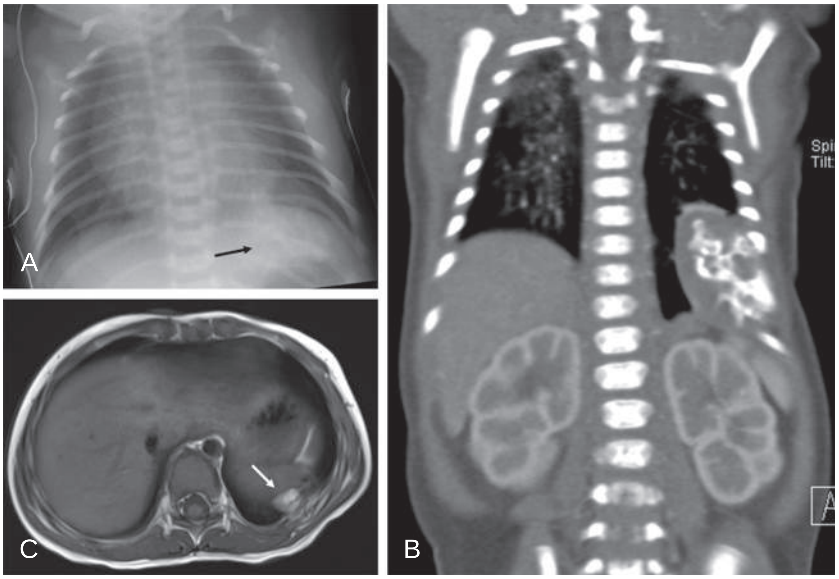

Figure 66-45 A 20-day-old infant with a prenatally diagnosed, calcified, left lower lung mass. Chest x-ray shows calcified mass (**A**, *arrow*) which on CT is seen to arise from posterolateral left ribs (**B**). T1-weighted MRI (**C**) shows presence of high signal intensity fat *(arrow)*, all consistent with the diagnosis of mesenchymal hamartoma.

malignancy of the chest wall in children.[177] Occurring in a younger population of children than thoracic Ewing sarcomas/PNETs, approximately 7% of pediatric rhabdomyosarcomas involve the chest wall and should be included in the differential diagnosis for a chest-wall mass occurring in children younger than the age of 10 years. Biopsy is necessary to make the diagnosis, and the imaging features are nonspecific, with considerable overlap between chest-wall Ewing sarcoma and rhabdomyosarcoma. Chest radiographs reveal a large unilateral chest mass, often with accompanying pleural thickening or effusion. As with Ewing sarcoma, there may be associated destructive rib changes. Cross-sectional imaging by either CT or MRI better delineates the extent of local disease spread. These tumors are heterogeneous in density on CT with variably increased signal on both T1- and T2-weighted MRI images. Contrast enhancement is heterogeneous, and these features likely reflect varying degrees of tumor necrosis. Tumor size, nodal status, and gross total tumor resection (upfront or delayed) have been shown to be significant predictors of event-free and overall survival. Tumors 5 cm or smaller were shown to be amenable to upfront surgical resection. Tumor size and the ability to achieve gross total resection were the strongest predictors of overall survival, with local recurrence after resection resulting in poor overall outcome.[179,180] As with other malignant sarcomas, FDG-PET has been used effectively in staging and response assessment in patients with rhabdomyosarcoma[181-184] and should be considered as an essential component of the imaging evaluation for these patients.

Mesenchymal Hamartomas

Mesenchymal hamartomas of the chest wall are rare, benign neoplasms occurring during infancy. The presence of a large chest-wall mass, often containing calcifications with associated rib destruction and chest-wall deformity should prompt this diagnosis. Because these lesions may contain a significant necrotic/cystic component, the distinction between Langerhans cell histiocytosis, lymphoma, and metastatic neuroblastoma may be difficult to make. These masses often become quite large, and the radiographic finding may be sufficient to suggest the diagnosis, showing a large calcified extrapleural mass with expansion/destruction of multiple ribs. CT or MRI allows more accurate measure of size, characterization of the soft-tissue component of the lesion, and mass effect on the lung and adjacent structures (Fig. 66-45).[185] In particular, the presence of hemorrhagic cystic components has been described as characteristic of these benign neoplasms.[185] There is some data to suggest that spontaneous resolution of these masses may also occur, although the extent of local invasion and tissue destruction may prompt surgical resection, which if complete, is usually curative. The importance of the imaging evaluation is to suggest this diagnosis in order to guide appropriate management of these benign lesions.

Pulmonary Metastases

Metastatic disease to the lung represents the most common pulmonary neoplasm encountered in childhood. The lung is a common site for metastatic disease spread but is an uncommon site in childhood for primary malignancy.

Extrathoracic pediatric tumors that are commonly associated with pulmonary metastases include Wilms tumor, rhabdomyosarcoma, hepatoblastoma, Ewing sarcoma, and osteosarcoma. Neuroblastoma does not typically result in hematogenously spread pulmonary metastases, although in its disseminated form, pulmonary metastases may be seen.

The imaging evaluation in a patient with a known primary malignancy with a propensity to metastasize to

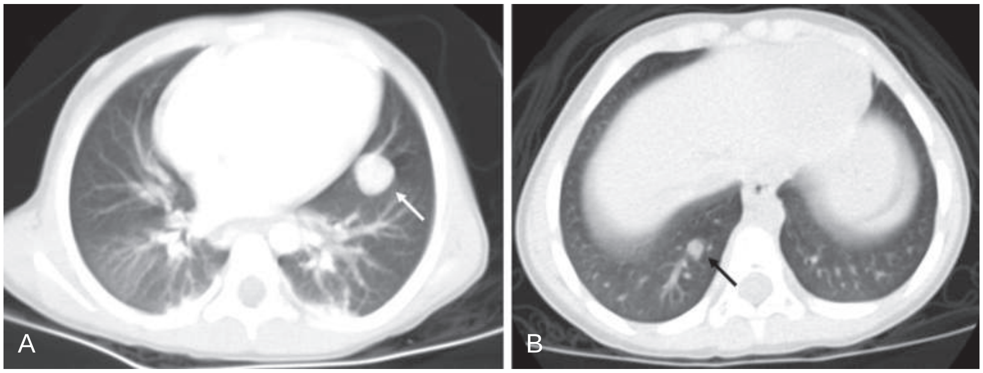

Figure 66-46 A 2½-year-old child with metastatic Wilms tumor. **A**, The nodule at the left lung base *(arrow)* was resected at diagnosis and found to be metastatic disease. **B**, The nodule at the right lung base discovered 1 year later was resected, and found to be a pulmonary hamartoma.

the lung should include chest CT. CT is more sensitive than conventional radiographs in detecting pulmonary metastatic disease, although the increased sensitivity of nodule detection has led to difficulty in distinguishing benign lesions from malignant pulmonary nodules (Fig. 66-46).[22,186] Once the staging evaluation has been completed and the absence of pulmonary metastatic disease and other sites of metastatic disease have been established, it may be reasonable to proceed with routine chest radiographs for subsequent follow-up care, reserving CT for patients with suspected relapse or at high risk for relapse. In particular, in osteosarcoma, which has a high frequency of developing pulmonary metastases and for whom resection of these metastases may be curative, routine follow up chest CT scanning is justifiable.

It is often difficult, particularly with small pulmonary nodules, to distinguish benign causes from malignancy.[22] Calcification within a pulmonary nodule is usually associated with benign causes (except in the case of osteosarcoma); however, there are no specific imaging findings that can be used to reliably make this distinction. Benign pulmonary nodules may result from postinflammatory change or represent small benign intrapulmonary lymph nodes. Short interval follow-up care and documentation of stability in areas of low suspicion is usually adequate to confirm the benign nature of these findings. For more suspicious or enlarging lesions, biopsy or surgical resection is necessary to arrive at a definitive diagnosis. The use of FDG-PET scanning has been advocated in an attempt to distinguish benign from malignant causes of pulmonary metastatic disease.[187] However, while CT can accurately identify lesions of only 1 to 2 mm in size, even the newest generation PET scanners have inherently lower limits of resolution, on the order of 5 mm, because of both the intrinsic spatial resolution of PET detectors and the distance traveled by positrons in the tissue before undergoing annihilation and emission of 511 keV coincident photons.

Controversy still exists as to the significance of pulmonary nodules detected by chest CT in patients with Wilms tumor.[188-190] There are conflicting data as to the importance of pulmonary nodules not visualized by chest radiography but detectable by chest CT in predicting relapse-free and overall survival in patients with Wilms tumor, with the most recent data from the National Wilms Tumor Study Group (NWTSG) 4 and 5 showing that patients with lung lesions visible only on CT have improved event-free, but not overall, survival and do not appear to benefit from pulmonary radiation.[191] Nonetheless it has been shown that the sensitivity of malignant nodule detection is enhanced by CT,[188,189] and current treatment protocols routinely advocate the use of chest CT in staging these patients. In an effort to develop a better understanding of CT features that might distinguish benign from malignant pulmonary nodules,[188] current Children's Oncology Group (COG) Wilms tumor protocols call for surgical resection or biopsy of persistent, suspicious lung nodules detected by CT in patients with intermediate and high-risk disease.

CT scanning of the chest for the purposes of identifying pulmonary metastatic disease need not include intravenous contrast, and the presence of hyperdense contrast material in small pulmonary vessels may confound the interpretation of a subtle parenchymal nodules. In addition, multidetector-row CT scanners allow the acquisition imaging data to be reviewed in 1-mm thick increments or less, as well as in sagittal and coronal planes. This allows the radiologist to make an accurate judgment as to the presence or absence of a suspicious pulmonary nodule and distinguish it from branching vessels. There is no data to suggest that additional high-resolution CT (HRCT) imaging, which is performed using a different image acquisition technique, provides any additional benefit or higher resolution over the 1-mm thick slices obtained during the multidetector helical acquisition.[192] MRI for the detection of pulmonary nodules has been shown to be feasible,[193-195] but there are no studies showing that MRI can replace CT for the routine identification of pulmonary metastatic disease.[196] Similarly low-dose attenuation-correction CT images of the lungs obtained as part of combined PET/CT examinations are not sufficient to exclude small pulmonary nodules, and a diagnostic chest CT obtained during suspended inspiration is still recommended for evaluation of patients at risk and in whom pulmonary metastases will impact clinical management.[197,198]

Although the imaging features of small pulmonary nodules may be nonspecific and the difficulty in distinguishing benign from nonneoplastic etiologies is challenging, the presence and persistence of lung nodules in a child with a solid tumor that has a propensity to metastasize to the lung is usually indicative of metastatic disease. The use of CT in detecting these sites of disease spread remains an essential component of the staging of most pediatric solid tumors.

GASTROINTESTINAL TUMORS

Tumors of the gastrointestinal tract, including the visceral abdominal organs, are relatively uncommon in childhood. In neonates, the majority of intraabdominal masses are not malignant. Children commonly have nonspecific complaints such as abdominal pain, weight loss, or failure to thrive. The imaging evaluation should begin with abdominal radiographs. These often provide valuable initial information, such as the presence of calcifications, mass effect on adjacent visceral organs, and the presence of bowel obstruction or perforation. Abdominal ultrasound is often used to gain further information about a suspicious mass. Doppler assessment may help distinguish cystic from solid masses and delineate patterns of blood flow in and around a tumor. These initial imaging studies are usually sufficient to narrow the initial differential diagnosis and to guide the subsequent imaging evaluation by CT, MRI, and/or PET.

Liver

Although rare in infants and young children, tumors of the hepatobiliary tract are the most common of the gastrointestinal tract tumors seen in childhood.[199-201] Usually a combination of diagnostic studies is obtained, including imaging findings, clinical findings, and serum markers, in order to arrive at a definitive diagnosis. Both benign and malignant tumors may be encountered. Hepatoblastomas are the most common primary malignant tumors in children under the age of 5.[201] Hepatoblastoma is usually encountered in infants and young children under the age of 3, with an average age at presentation of 16 months. At diagnosis the mass is typically quite large (greater than 10 cm).

Metastatic disease is encountered in approximately 20% of the patients, with pulmonary metastases most common. The imaging evaluation should be directed at determining surgical resectability, establishing sites of metastatic disease, and monitoring response to chemotherapy. More than 90% of the children have elevated α-fetoprotein (AFP) levels at diagnosis; the presence of metastatic disease, high AFP levels, and a high PRETEXT stage of liver involvement by tumor are all associated with poor outcome.[202-204] Surgical resection alone is insufficient to achieve cure in most cases, and the combination of surgery and chemotherapy has resulted in 5-year overall survival rates of over 70%.[204]

Abdominal radiographs typically show an abdominal mass. Calcifications may be present, and pulmonary masses may be visible at the time of diagnosis at the lung bases (Fig. 66-47). Ultrasound should be the initial imaging test in a child with an abdominal mass and in hepatoblastoma reveals a large echogenic, intrahepatic

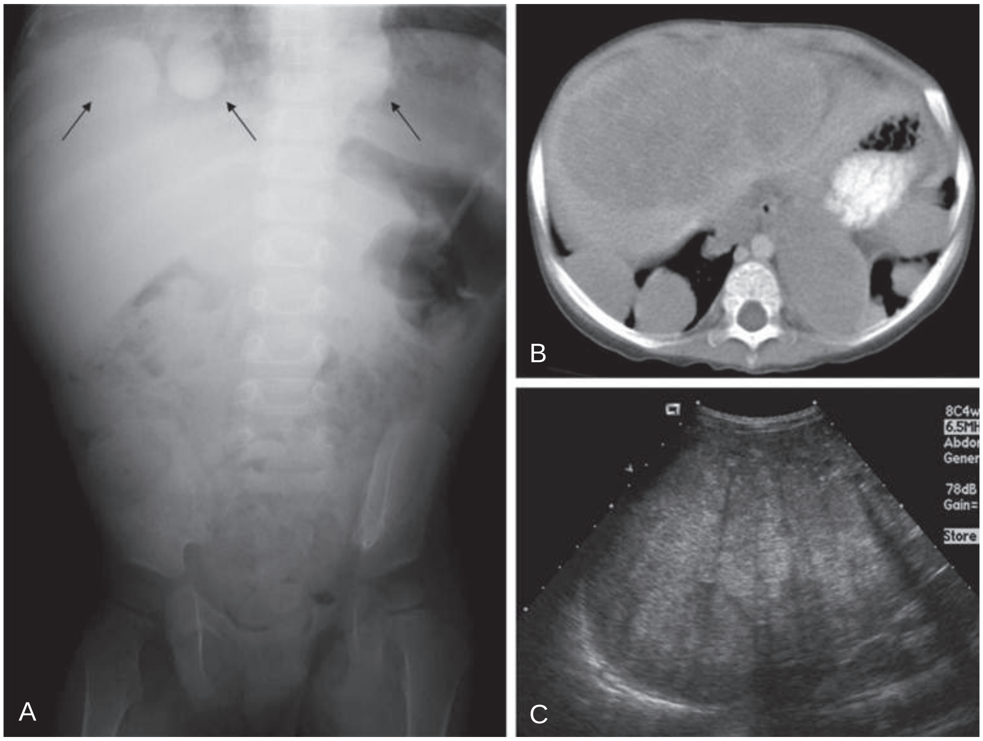

Figure 66-47 Hepatoblastoma. A 15-month-old patient with an abdominal mass found during the physical examination. **A**, Note lung metastases on the abdominal radiograph *(arrows);* **B**, extensive disease depicted on CT; and **C**, the difficulty discriminating the large echogenic mass from normal liver on ultrasound.

mass. It may be difficult with very large masses to define a margin between the hepatoblastoma and normal hepatic parenchyma (see Fig. 66-35). Hypoechoic areas may relate to necrosis or hemorrhage. Color Doppler imaging and pulsed-wave Doppler should be used routinely to assess for intravascular extension of tumor,[201,203] IVC invasion, and portal vein thrombosis, both of which may affect eligibility for liver transplantation.[205]

CT and or MRI are important to better define the relationship of the intra-hepatic mass to adjacent vascular structures, adjacent organs, and to determine the extent of hepatic involvement and surgical respectability.[203] This is best accomplished with biphasic CT or MR angiographic techniques and imaging should include scanning after early arterial and portal venous phases of contrast opacification, since small satellite lesions may only be visible on the early arterial phase imaging (see Fig. 66-2).[206] Typically, hepatoblastomas show a heterogeneous pattern of enhancement. Multiplanar reconstructions are also crucial, both in aiding surgical planning and in better delineating invasion into adjacent vascular structures (i.e., IVC invasion; portal venous thrombosis). MRI imaging typically shows heterogeneously T2-hyperintense lesions with variable patterns of enhancement after gadolinium contrast administration (Fig. 66-48). MRI may be of particular value in delineating subtle lesions that are inconspicuous on contrast enhanced CT scanning. The use of hepatobiliary contrast agents, which are taken up by normal functioning liver tissue but not by malignant liver lesions, as well as diffusion-weighted imaging, can further enhance lesion detection and characterization.[207] As shown in Fig. 66-49, the hepatobiliary agent gadoxetate (Eovist) identifies a poorly enhancing lesion on a background of normally enhancing hepatic parenchyma in a patent with unresectable hepatoblastoma.

The PRETEXT staging system was developed by the International Childhood Liver Tumors Strategy Group (SIOPEL) in an effort to develop a pretreatment imaging-based measurement of disease burden and surgical resectability as a basis for staging and risk stratification of children with hepatoblastoma.[203] In the PRETEXT system of staging the liver is divided into sections, based in part on Couinaud's system of segmental anatomy. PRETEXT staging is based on the number of adjacent liver sections involved with tumor (Table 66-1) and has been shown to be effective in predicting resectability and overall survival in patients who complete neoadjuvant chemotherapy.[208] Because the PRETEXT staging system relies almost entirely on the pretreatment imaging assessment, it is essential that MRI and/or CT scanning be performed using optimal scanning parameters (i.e., multiphasic technique, properly timed contrast bolus, sedation to minimize motion artifact) in order to provide and accurate assessment of the extent of liver involvement. The COG staging system, used widely throughout North America, historically had relied on intraoperative and postoperative assessment, with less dependence on preoperative imaging.[203] However, current protocols have adopted the SIOPEL recommendations for PRETEXT characterization to monitor response to neoadjuvant chemotherapy and determine surgical resectability.[209,210]

The presence of a rising AFP level in a patient previously free of detectable disease should prompt a thorough investigation to identify sites of recurrent disease. The detection of recurrent hepatoblastoma after chemotherapy and surgical resection may be challenging with conventional cross-sectional imaging techniques. Although there has been relatively little published experience using FDG-PET scanning to monitor early sites of disease recurrence, there are reports suggesting FDG-PET and/or CT can improve both the sensitivity and specificity of identifying early foci of disease recurrence.[72,211,212] Characterization by FDG-PET of unusual sites of disease relapse or equivocal abnormalities on CT and/or MRI

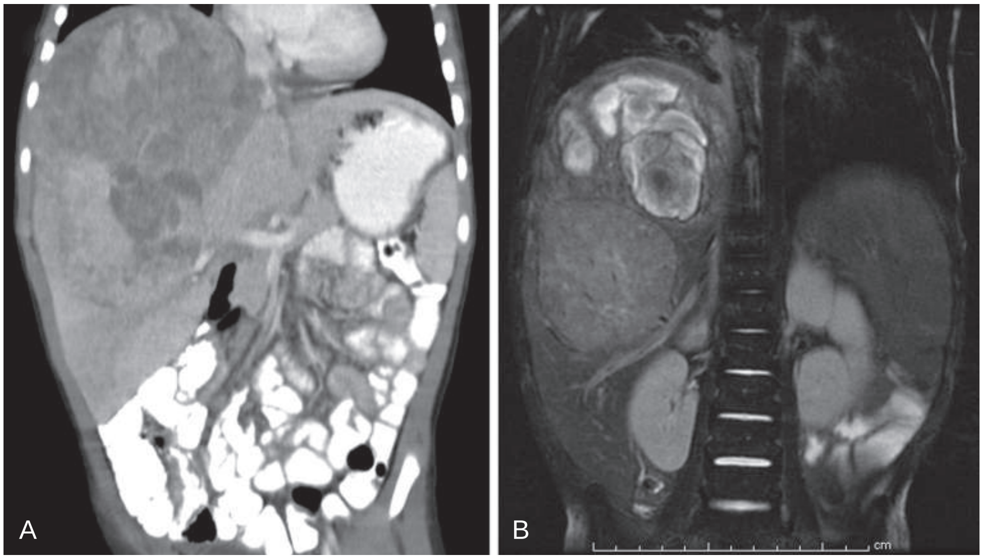

Figure 66-48 A 3-year-old patient with hepatoblastoma, showing superiority of MRI (**B**) in detecting the extent of liver involvement and the relationship to adjacent structures, as compared with CT (**A**).

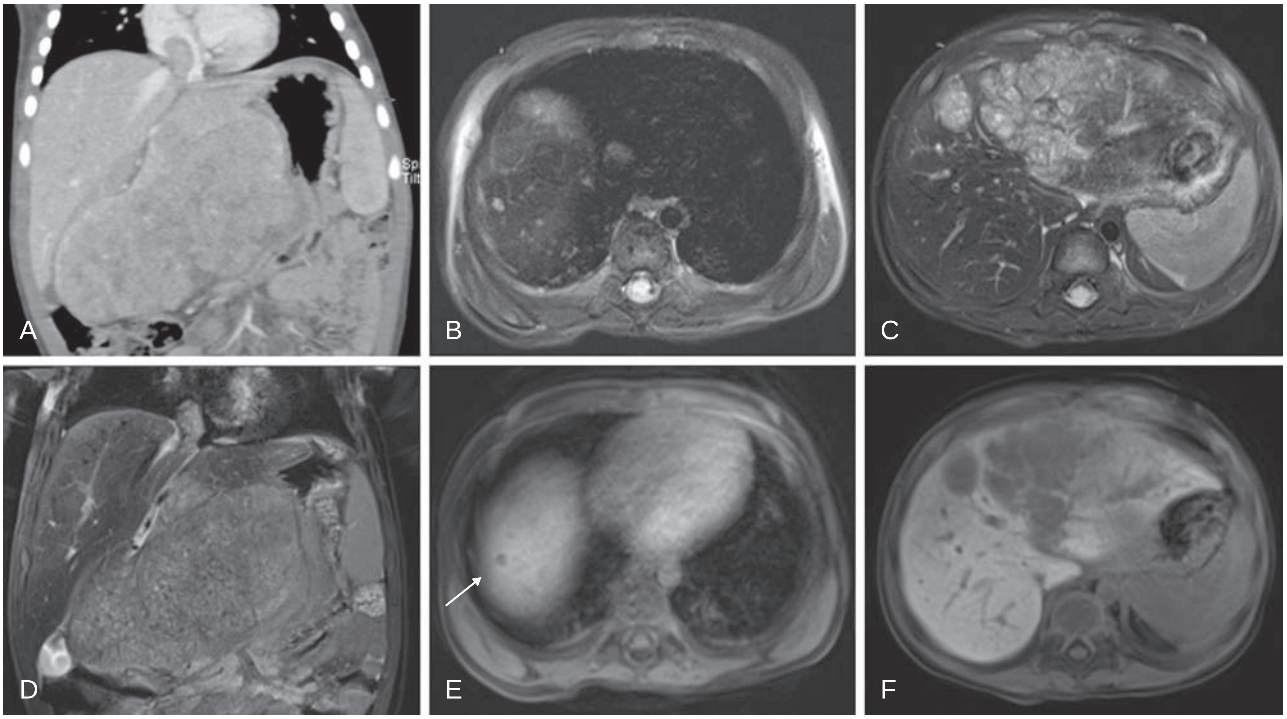

Figure 66-49 A 17-month-old infant with hepatoblastoma. CT angiogram (**A**), fat-suppressed T2-weighted (**B** and **C**) and contrast enhanced MRI (**D-F**) show a large exophytic liver mass with extension into the right atrium. Delayed postcontrast images after administration of the hepatocyte selective contrast agent gadoxetate (Eovist) identifies an additional tiny satellite lesion near the liver dome (**E,** *arrow*).

TABLE 66-1 Childhood Liver Cancer (Hepatoblastoma): PRETEXT Staging System[208]

Tumor Stage	Description
1	Tumor involves only one quadrant. Three adjoining liver quadrants are free of tumor.
2	Tumor involves two adjoining quadrants. Two adjoining quadrants are free of tumor.
3	Tumor involves three adjoining quadrants or two nonadjoining quadrants. One quadrant or two nonadjoining quadrants are free of tumor.
4	Tumor involves all four quadrants. There is no quadrant free of tumor.
Extrahepatic Considerations	
	V+: Involvement of the inferior vena cava and/or all three hepatic veins
	P+: Involvement of the main portal vein and/or both left and right branches
	E+: Extrahepatic disease in the abdomen
	M+: Distant metastases

PRETEXT, Pretreatment Extent of Disease.

may confirm the presence of metabolically active disease and guide subsequent treatment decisions (Fig. 66-50).

Hepatocellular Carcinomas

Hepatocellular carcinoma, although rare in childhood, is the second most common primary hepatic malignancy. It typically occurs in older children, with a mean age at diagnosis of approximately 12 years.[202] There is a slight male predominance and an association between development of hepatocellular carcinoma and preexisting liver disease, such as hepatitis B, biliary atresia, and Fanconi syndrome, as well as certain metabolic diseases such as hereditary tyrosinemia and glycogen storage disease.[202] The imaging features of hepatocellular carcinoma are not unique, and as for hepatoblastoma, ultrasound examination is often the first imaging study performed. Multiphase CT scanning with multiplanar reconstruction affords the greatest likelihood of detecting subtle lesions and in assessing relationships to adjacent structures and the vasculature,[200,206] although the use of diffusion-weighted MR imaging and hepatobiliary MR contrast agents has added to the appeal of MRI for evaluating these patients.[44,213] The CT appearance of hepatocellular carcinoma depends on tumor size and phase of contrast administration. Lesions are typically isointense or mildly hypointense relative to liver and show hyperattenuation on early arterial phase scanning, becoming isointense during later venous phases of imaging (Fig. 66-51). Early arterial phase, portal venous phase, and

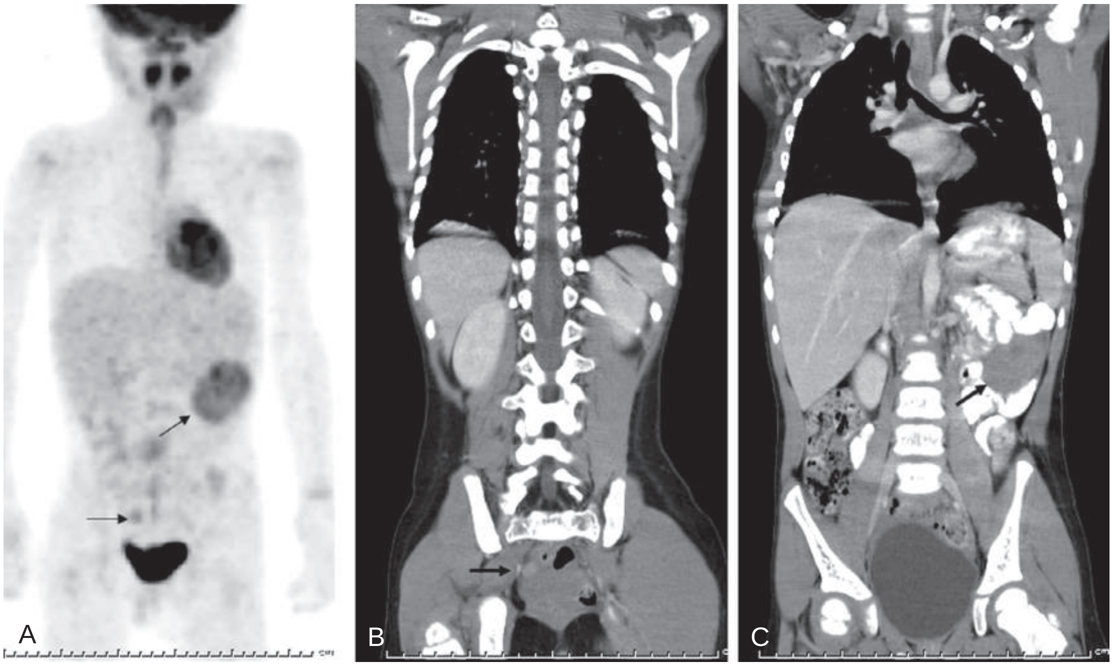

Figure 66-50 A 5-year-old girl with metastatic hepatoblastoma who had undergone resection of the primary mass. The patient was in remission with new rising AFP levels. FDG-PET (**A**) shows two foci of uptake *(arrows),* corresponding to soft-tissue masses on CT in the mesentery (**B**) and deep pelvis (**C**, *arrows*). Surgery confirmed metastatic disease.

delayed equilibration venous phase images have all been shown to contribute to enhancing lesion conspicuity, providing the greatest sensitivity and specificity in lesion detection.[214] MR imaging, with opposed-phase imaging to detect microscopic fat and hepatobiliary agents to identify lesions with hepatocyte function can help in distinguishing hepatocellular carcinoma from benign liver lesions such as hepatic adenoma and focal nodular hyperplasia (FNH)[201]; however, biopsy may still be necessary to confirm the diagnosis (Fig. 66-52). Gadolinium-enhanced MRI, like CT, shows hyperenhancing lesions during early arterial phase imaging, with larger tumors showing variable signal intensity and patterns of enhancement[215] and absent enhancement on delayed hepatocyte phase imaging when hepatobiliary agents are used. Superparamagnetic iron-oxide particles, which are taken up by Kupffer cells present in normal liver and in FNH, have been used to help differentiate hepatocellular carcinoma, which contains few if any Kupffer cells, from benign liver masses and to enhance lesion conspicuity relative to the surrounding liver tissue.[215]

The fibrolamellar form of hepatocellular carcinoma occurs in adolescents and has imaging features that are distinctive, showing a central scar and often associated with calcification (Fig. 66-53). Fibrolamellar hepatocellular carcinoma is not associated with elevated AFP, and overall survival is higher than in other forms of hepatocellular carcinoma, in part because of its presentation as a solitary localized mass amenable to complete surgical resection.[216] Ultrasound reveals a hypoechoic mass, often

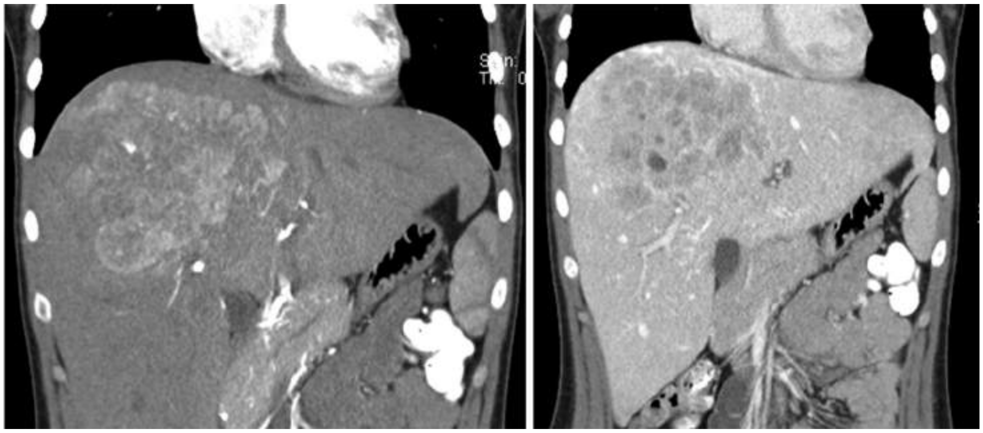

Figure 66-51 An 18-year-old female with fibrolamellar hepatocellular carcinoma. Biphasic contrast-enhanced CT demonstrates a large hyperenhancing lesion in the right lobe, which on delayed images becomes hypodense and less distinct from the background liver tissue.

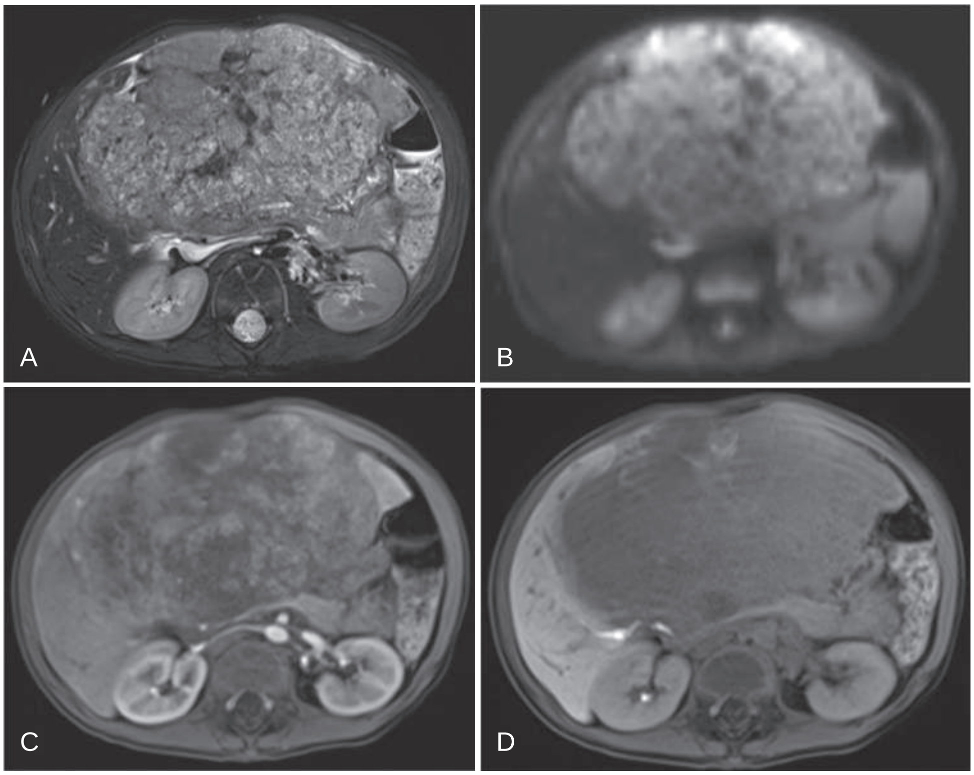

Figure 66-52 A 19-month-old child with hepatocellular carcinoma. T2-weighted (**A**) and DWI (**B**) images show a large heterogeneous mass in the left liver lobe with restricted diffusion. **C**, After Gd-contrast administration with gadoxetate (Eovist), early dynamic images shows heterogeneous enhancement. **D**, Delayed imaging shows absence of gadoxetate (Eovist) enhancement on the hepatocyte phase, in contrast to the enhancement of the adjacent normal liver.

with a focal central hyperechoic scar. After the initial characterization by ultrasound, CT or MRI is indicated for further staging. On CT, fibrolamellar hepatocellular carcinoma is usually relatively low attenuation, well-circumscribed mass with heterogeneous enhancement, initially becoming hyperintense relative to the surrounding liver parenchyma and ultimately becoming isointense to the liver during the equilibration phase of scanning. A nonenhancing central scar is seen in the majority of the cases (see Fig. 66-53).[217] On MRI, lesions are isointense to hypointense relative to the liver on T1-weighted images and isointense to hyperintense on T2-weighted sequences. The pattern on gadolinium enhancement is similar to that observed on CT, with lesions becoming hyperintense early after contrast infusion and ultimately isointense to liver on delayed scanning. The distinction between fibrolamellar hepatocellular carcinoma and FNH, both of which have similar imaging characteristics and patterns of early contrast enhancement, may be difficult to make (compare Figs. 66-53 and 66-54). However, as shown in Figure 66-54, the uptake and retention of a hepatobiliary contrast agent by the lesion on delayed hepatocyte phase imaging is nearly diagnostic of FNH.[213]

Embryonal Sarcomas (Hepatic Mesenchymomas)

Embryonal sarcomas of the liver are the fourth most common hepatic neoplasm in children after hepatoblastoma, hepatocellular carcinoma, and infantile hepatic hemangioma. These tumors are highly malignant, usually present in later childhood (between the age of 6 and 10), and are typically accompanied by symptoms of abdominal pain and an abdominal mass. Embryonal sarcomas may be difficult to distinguish from mesenchymal hamartomas, although the latter tumors are more commonly diagnosed before the age of 2 years. At presentation embryonal sarcomas are often large and contain both cystic and solid areas with areas of necrosis. Ultrasound reveals a heterogeneous echogenic mass with many features overlapping with mesenchymal hamartoma and infantile hemangioma. Calcifications are rare. CT reveals a large hypodense mass, often with septations and areas of internal high attenuation; MRI shows a high signal-intensity lesion on T2-weighted images (Fig. 66-55), with predominantly low signal on T1-weighted images. After contrast enhancement, imaging by either CT or MRI demonstrates peripheral enhancement and central areas of heterogeneous signal intensity that likely reflect solid tumor elements, cystic spaces, necrosis, and foci of hemorrhage.[218] Despite being highly malignant, complete surgical resection and adjuvant chemotherapy can be curative in the majority of these patients.[202,219]

Mesenchymal Hamartomas

Mesenchymal hamartoma, in contrast to hepatoblastoma, is a predominantly cystic mass most often occurring in infants under the age of 2 years. It commonly

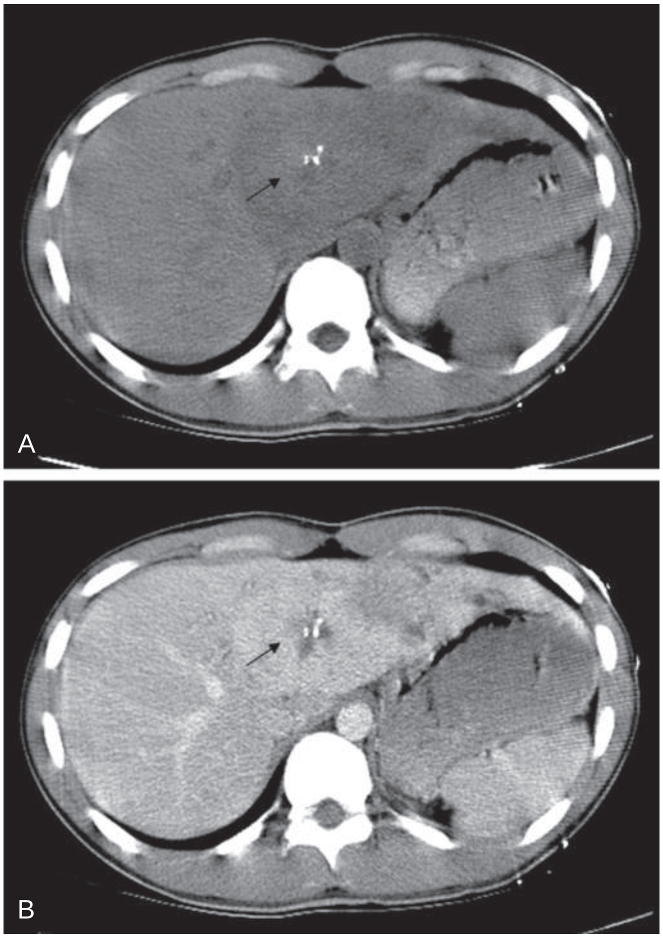

Figure 66-53 A 16-year-old patient with fibrolamellar hepatocellular carcinoma. Unenhanced (**A**) and contrast enhanced (**B**) CT show the calcifications and poorly enhancing central scar *(arrows)* typical of this form of hepatocellular carcinoma.

presents as a painless, palpable abdominal mass comprised of mesenchymal tissue, bile ducts, hepatocytes, and hematopoietic cells. In contrast to hepatoblastoma, which is the primary differential consideration in an infant, the AFP levels are normal. On imaging, radiographs reveal a large right upper quadrant mass. Calcifications, which are seen in hepatoblastoma, are unusual in mesenchymal hamartoma.[201] Ultrasound examination typically shows a complex, predominantly cystic mass. MRI and CT may be of value in further characterizing the lesion and typically show large multilocular cystic masses with septations. Only minimal enhancement is seen. Some of the masses may have a predominantly solid component yielding a so-called Swiss cheese appearance to the mass, and contributing to some difficulty in the differential diagnosis. MRI may also demonstrate the complex nature of the cystic fluid, with gelatinous, more complex fluids showing high signal on T1-weighted images instead of the more common T2 bright/ T1 dark serous fluid contained in the majority of the cysts (see Fig. 66-55). Treatment is surgical resection, and recurrence is uncommon.[202]

Infantile Hepatic Hemangiomas

Infantile hepatic hemangioma are proliferative endothelial cell neoplasms that may be solitary or may diffusely involve the liver. Infantile hepatic hemangiomas have characteristic phases of cellular proliferation followed by spontaneous involution. They are often referred to as *hepatic hemangioendothelioma*, creating some confusion in nomenclature and must be distinguished from epithelioid hemangioendothelioma.[220] The latter is a proliferative tumor with malignant potential that does not involute in contrast to the benign hepatic hemangioma. Infantile hepatic hemangiomas share the same growth characteristics as the more common cutaneous infantile hemangiomas. The majority present by 6 months of age, and about half are associated with cutaneous lesions. The majority of the infantile hepatic hemangiomas involute spontaneously, and adverse outcomes are only observed when there is massive hepatic involvement and arteriovenous (AV) shunting with accompanying high-output cardiac failure. The presence of extensive hepatic involvement and near complete replacement of the liver parenchyma occurs in the diffuse infantile hemangioma variant and is associated with profound hypothyroidism secondary to overproduction of type III iodothyronine deiodinase.[221]

Ultrasound is usually the first step in the evaluation and typically shows either focal or multiple hepatic masses with heterogeneous echotexture. It may be possible to identify a large draining varix or varices. Both arterial and venous waveforms are often detected, and calcifications may be present. More characteristic findings are seen on CT and MRI. MRI typically shows homogeneously hypointense lesions on T1-weighted imaging with heterogeneous hyperintense masses on T2-weighted images. After contrast enhancement, imaging by either CT or MRI reveals a typical pattern of peripheral contrast enhancement with gradual filling in centrally (centripetal enhancement) (Fig. 66-56, *A* and *B*).[222] Diffuse infantile hepatic hemangiomas may nearly completely occupy the entire liver parenchyma (see Fig. 66-56, *C* and *D*). The associated hypothyroidism is the result of the elaboration of deiodinase enzymes affecting thyroid hormone synthesis, which can in turn result in cardiac failure and neurologic impairment. These endocrinologic findings are important in securing the diagnosis, because the multiple hepatic masses may share overlapping imaging features with malignant hepatic lesions such as hepatoblastoma or metastatic neuroblastoma.

High-output cardiac failure associated with large varices and significant high-volume AV shunting can be effectively treated using interventional radiologic techniques, including coil and particle embolization. This may be essential in stabilizing the patient in order to initiate treatment to accelerate the involution of these benign proliferative lesions.[220]

Hepatic Adenoma

Other benign hepatic lesions include solitary hepatic adenomas. Hepatic adenomas are unusual in children in the absence of a predisposing condition, such as glycogen storage disease, galactosemia, or tyrosinemia. The

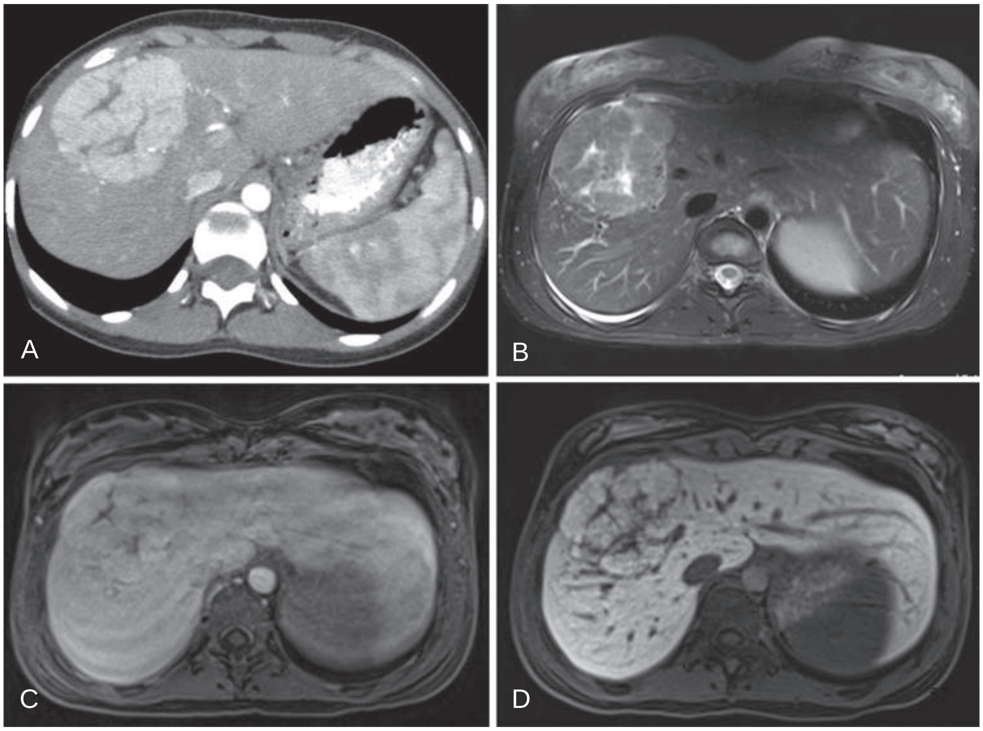

Figure 66-54 A 15-year-old patient with abdominal pain and a liver mass noted on outside CT (**A**). **B**, MRI performed with gadoxetate (Eovist) shows a mildly T2-hyperintense lesion that becomes isointense to liver shortly after contrast infusion (**C**), but that retains the contrast on delayed hepatocyte phase imaging (**D**). The features, together with the central nonenhancing scar, are characteristic of FNH.

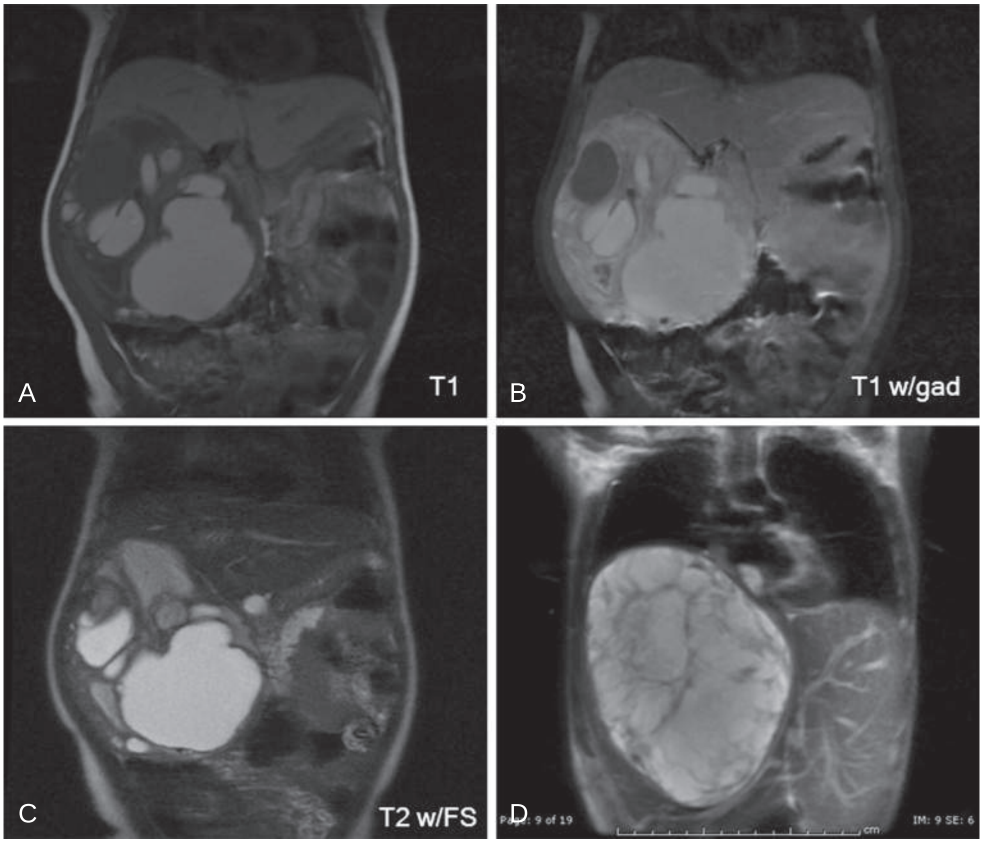

Figure 66-55 Mesenchymal hamartoma. MRI showing the complex nature of the multiple cysts in a 13-month-old infant with mesenchymal hamartoma. Note the importance of obtaining T1-weighted images before contrast administration (**A** and **B**), in addition to fluid-sensitive T2-weighted sequences (**C**), because areas of complex fluid may be T1 bright and should not be misinterpreted as enhancing solid components of the mass. Note the similarity to the large embryonal sarcoma shown in (**D**).

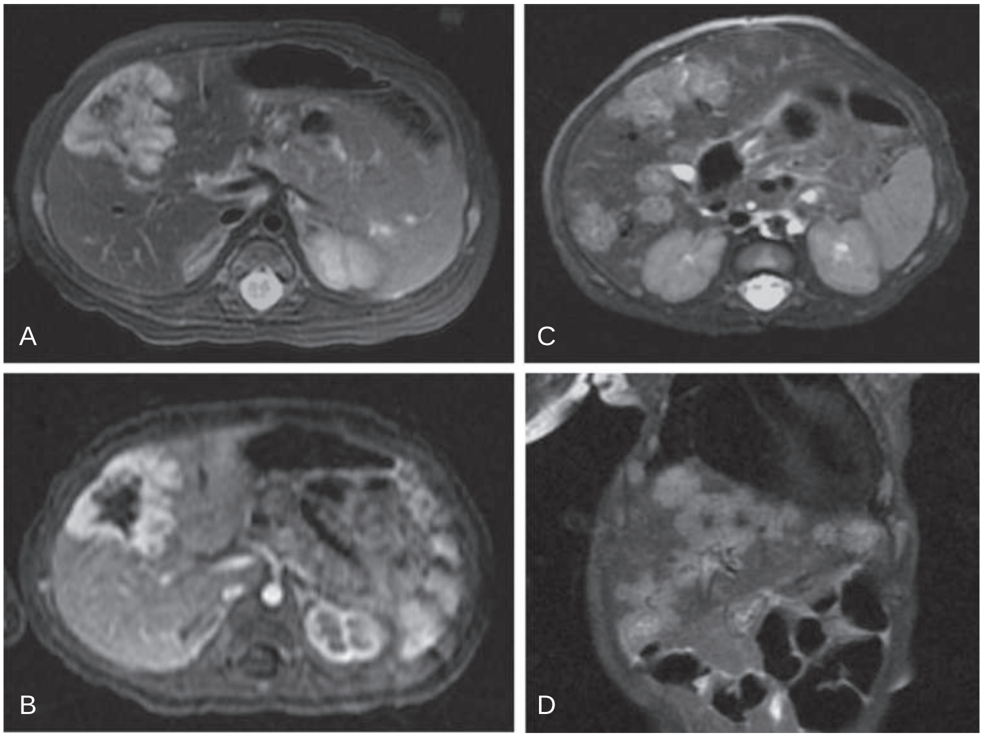

Figure 66-56 Involuting hepatic hemangioma and diffuse infantile hemangioma. Fat-suppressed T2-weighted (**A** and **C**) and post–gadolinium-enhanced (**B** and **D**) MRI showing large solitary peripherally enhancing lesion typical of involuting hepatic hemangioma (**A** and **B**) and the multifocal hepatic involvement in a patient with hypothyroidism and diffuse infantile hemangioma (**C** and **D**).

imaging features of hepatic adenomas are not specific, and imaging is usually directed at monitoring these lesions for increases in size and number. Rapid increase in size is generally considered to be an indication of degeneration of benign adenoma to hepatocellular carcinoma, particularly in patients with glycogen storage disease.[223] Regular surveillance, typically by ultrasound, is indicated in these patients. MRI should be considered to further aid in characterizing new or multiple lesions.

Focal Nodular Hyperplasia

FNH is rare in children, most commonly occurring in teenage and adolescent years.[224] It is usually found incidentally during imaging evaluation for other reasons. This benign lesion typically shows a central fibrous scar with surrounding hyperplastic hepatocytes and small bile ducts. As discussed, these imaging features are also seen in the fibrolamellar variant of hepatocellular carcinoma, and the distinction between FNH and fibrolamellar hepatocellular carcinoma may be difficult. CT and MRI scans usually show rapid homogeneous contrast enhancement during early arterial-phase imaging (see Figs. 66-53 and 66-54). Lesions then characteristically become isodense to the liver during later phases of enhancement, with the central scar remaining hypodense even during the delayed imaging period. With newer MRI imaging techniques performed either with iron-oxide particles that accumulate in reticuloendothelial cells (Kupffer cells) present in the hyperplastic FNH lesions or with hepatocyte selective gadolinium based agents such as gadoxetate (Eovist), the diagnosis of FNH[213,224] can generally be made with confidence. For equivocal cases, scintigraphy with ^{99m}Tc-sulfur colloid can also be performed, although in practice this is rarely necessary. These masses may be monitored by ultrasound to ensure stability and do not typically require surgical resection unless they become symptomatic or undergo progressive enlargement. FNH has also been observed in patients who have completed therapy for nonhepatic primary tumors.[225-227] Whereas larger masses may be by detected by ultrasound or CT, it has been found that dynamic contrast-enhanced MRI is a highly sensitive technique for identifying these lesions. Occasionally these lesions can be characterized by ultrasound using high-resolution, high-frequency transducers; however, they are unequivocally shown by contrast-enhanced MRI (Figs. 66-57 and 66-58). These FNH lesions are also isointense to the liver on conventional imaging sequences and display rapid early arterial enhancement, after which they become nearly isointense to the liver and indistinguishable from the surrounding parenchyma. Hepatobiliary contrast agents are now used routinely to further characterize these lesions as benign FNH (see Fig. 66-53) and distinguish them from hepatic metastatic deposits. It is important recognize these characteristic patterns of enhancement so as to not mistake this benign entity for recurrent disease or a new site of disease relapse.

Other lesions occurring in the liver include sarcomatous tumors such as malignant angiosarcomas and rhabdomyosarcomas of the biliary tree, malignant vascular tumors, and metastatic disease. The most common metastatic lesions occurring in the liver include neuroblastomas, locally invasive and hematogenously-disseminated

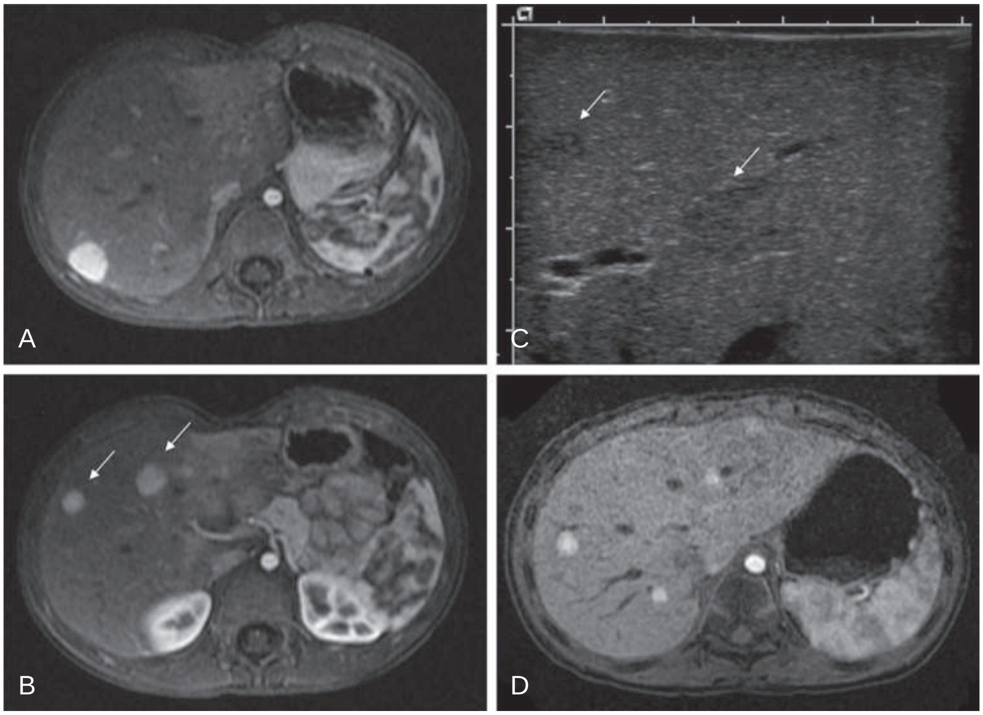

Figure 66-57 A 19-month-old boy with a history of treatment for stage 4 neuroblastoma. Follow-up MRI imaging using dynamic contrast enhancement shows multiple brightly enhancing lesions throughout the liver (**A** and **B**). These rapidly become isointense to liver during delayed scanning. They are not seen on any other sequences. The enhancement characteristics are typical of FNH. Intraoperative ultrasound localized lesions for biopsy (**C**) and confirmed them as FNH. Similar lesions in a 2-year-old patient treated in infancy for stage 4 neuroblastoma are shown in **D**.

Wilms tumors, rhabdomyosarcomas and Ewing sarcomas.[201] The imaging characteristics of these metastatic hepatic lesions are nonspecific with lesions characteristically hypoechoic on ultrasound relative to normal liver parenchyma, decreased attenuation on CT scan, low T1 and increased T2 signal intensity on T1- and T2-weighted MR images, respectively, and variable patterns of contrast enhancement with both CT and MRI.

Spleen

Primary tumors of the spleen are exceedingly rare.[228] Angiosarcomas have been reported but are not common in childhood. Involvement of the spleen by lymphoma and lymphoproliferative disease is the most common cause of malignant infiltration of the spleen.[229] Imaging evaluation by ultrasound often demonstrates multiple or

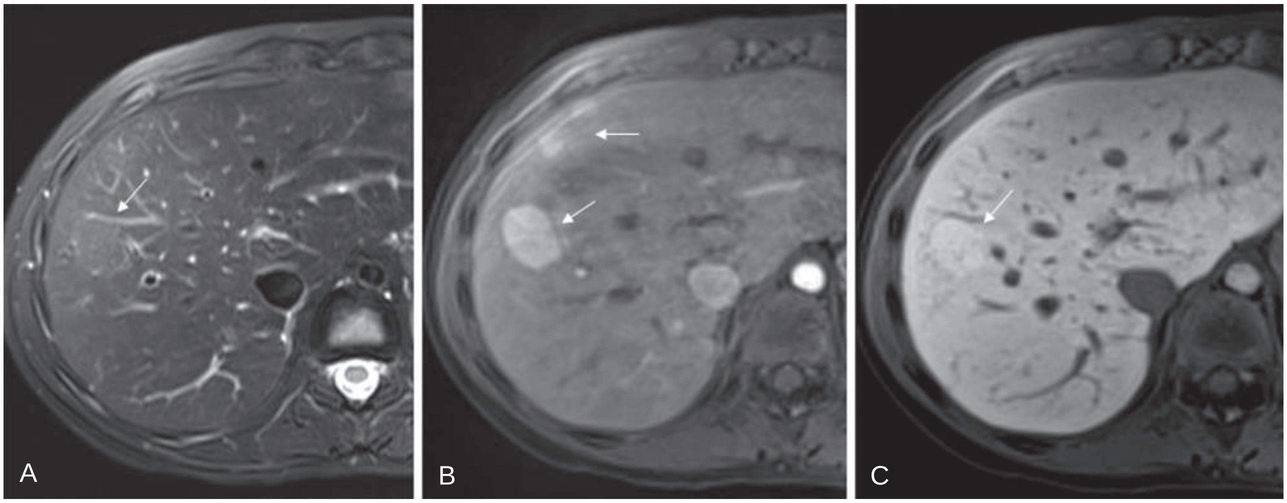

Figure 66-58 A 6-year-old patient treated for stage 4 neuroblastoma as an infant who developed multiple enhancing liver lesions proven to be FNH on biopsy. Subsequent MRI with gadoxetate (Eovist) shows representative lesions *(arrows)* to be isointense to liver on T2-weighted imaging (A), hyperenhancing on an early–arterial-phase image (**B**), and with persistent enhancement on the 20-minute delayed hepatocyte phase sequence (**C**). These features are characteristic of FNH.

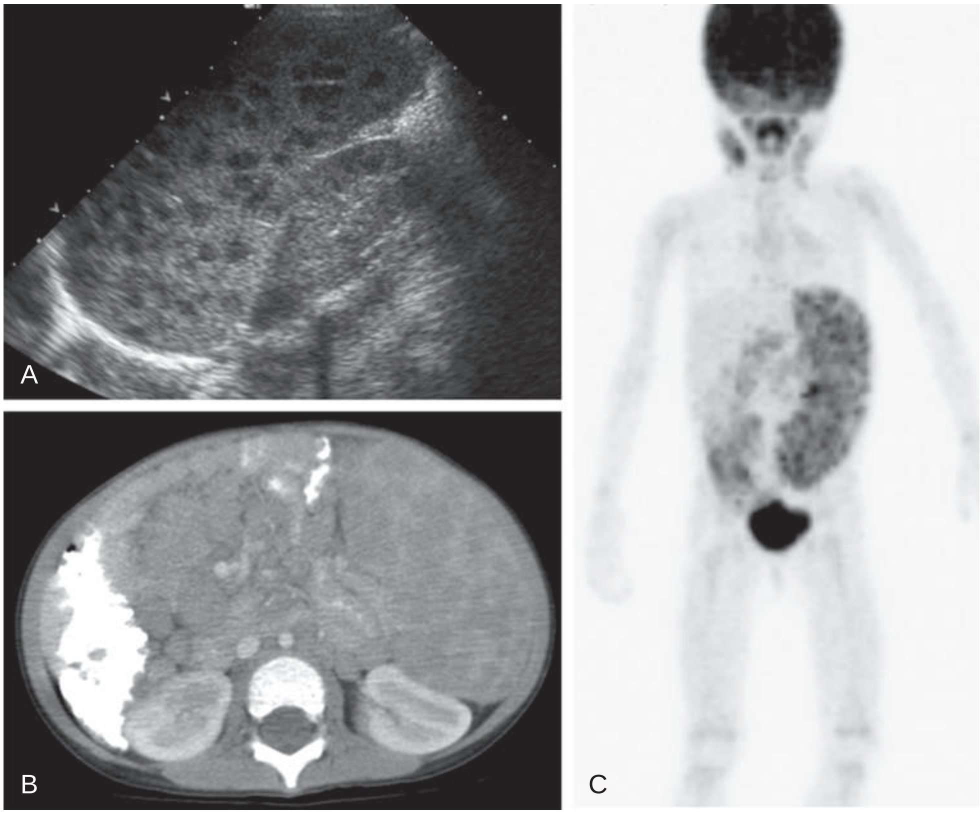

Figure 66-59 Lymphoproliferative disease. Ultrasound (**A**) and CT (**B**) demonstrate extensive splenic involvement and massive adenopathy in a patient with an unclassified lymphoproliferative disease. FDG-PET (**C**) shows multiple sites of disease and in particular confirms the extensive abnormalities in the spleen.

solitary hypoechoic masses (Fig. 66-59). CT scanning may be equivocal because of variable phases of splenic parenchymal enhancement. MRI, in contrast, can be very sensitive at detecting focal lesions that are occult by a CT and/or ultrasound. In the setting of lymphoma and lymphoproliferative disease, FDG-PET imaging has been shown to be an effective adjunctive imaging modality for detecting splenic involvement.[230,231] This is of importance both in determining the patient's stage of disease at diagnosis and in identifying sites of disease to be watched and assessed for response after treatment. In addition, the negative predictive value of PET/CT in discriminating between benign and malignant lesions has been emphasized both in patients with coexistent malignant disease and in patients without history of malignancy in whom a solid splenic mass is identified by other imaging techniques.[232]

Biliary Tract

Tumors of the gall bladder and bile ducts are rare in children, and include biliary rhabdomyosarcomas and cholangiocarcinomas, the latter of which occur in the setting of chronic ulcerative colitis. The initial imaging evaluation is usually by ultrasound, often for symptoms of biliary-tract obstruction such as pain, jaundice, and weight loss. Ultrasound may show evidence of bile-duct dilation and biliary-tract obstruction; however, identification of a focal mass usually requires additional evaluation by MRI/magnetic resonance cholangiopancreatography (MRCP), with diagnostic confirmation by endoscopic retrograde cholangiopancreatography (ERCP). Particularly in the setting of rhabdomyosarcoma, FDG-PET is of value in accurately determining the stage of disease.[184] Biliary rhabdomyosarcoma can arise from the intrahepatic or extrahepatic biliary bile ducts, gallbladder, cystic duct, or ampulla of Vater. At the time of presentation with obstructive jaundice and abdominal pain, these neoplasms are usually quite large, and as a result the distinction between biliary rhabdomyosarcoma, primary hepatic tumors arising in the hepatic hilum, pancreatic neoplasms, and renal/suprarenal masses may be challenging (Fig. 66-60).[233]

Pancreas

Primary tumors of the pancreas are rare in children, in contrast to adults. In addition, the types of tumors found in children differ from the adult tumors, in whom adenocarcinomas predominate. Pancreatic tumors can be classified into nonfunctional tumors of the exocrine pancreas and functional tumors of the endocrine pancreas, as well as secondary metastatic pancreatic neoplasia.[234]

Malignant epithelial neoplasms arising from the exocrine pancreas include pancreatoblastomas, and solid papillary epithelial neoplasms of the pancreas. Primary nonepithelial tumors of the pancreas are very rare and include lymphomas, rhabdomyosarcomas and primitive

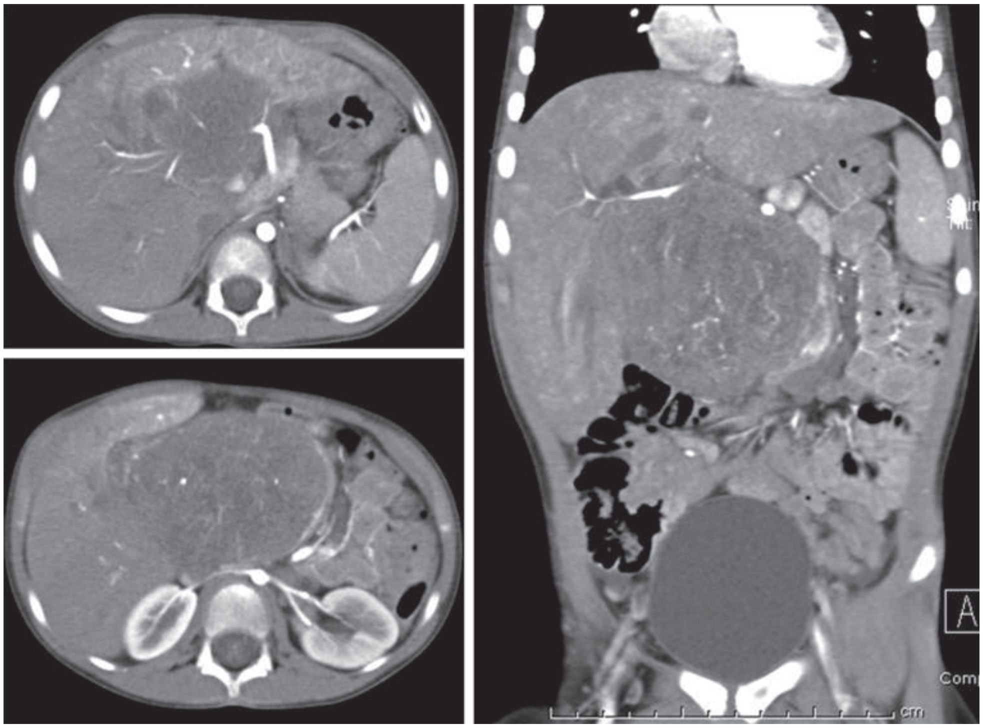

Figure 66-60 Biliary rhabdomyosarcoma. Dynamic contrast-enhanced CT reveals a large mass in the hepatic hilum, encasing the vessels and infiltrating adjacent structures. Note the lack of significant bile duct dilation, allowing the mass to become very large before producing symptoms of obstructive jaundice.

neuroectodermal tumors. Pancreatic endocrine neoplasms are rare in children, and they are usually associated with the multiple endocrine neoplasia syndrome. These include hormonally active tumors such as insulinomas, gastrinomas, VIPomas and glucagonomas.

Pancreatoblastomas

Pancreatoblastomas can occur at any age but are most common in children between the ages of 1 and 8 years. Pancreatoblastomas are reported as arising in or around the head of the pancreas in roughly half of the cases. Because they are nonfunctional, they are typically quite large at the time of diagnosis. Presenting symptoms include abdominal pain, nausea, and weight loss. Obstructive symptoms such as jaundice or pancreatitis are less common despite the large size of these masses, which has been attributed to the soft, gelatinous, and compliant consistency of these tumors.[235] These tumors are typically well encapsulated, have heterogeneous patterns of echogenicity on ultrasound, and show variable patterns of contrast enhancement on CT (Fig. 66-61). Calcifications are commonly seen and are probably the sequelae of hemorrhage and necrosis known to occur within these tumors. MRI shows a similar pattern of heterogeneous signal intensity and enhancement, with masses usually hypointense on T1-weighted images and variably hyperintense on T2-weighted and post–gadolinium-enhanced images. As with hepatoblastoma, pulmonary metastatic disease is often present, and the staging evaluation must include a CT of the chest. Because of their large size, the tissue of origin may be difficult to clearly delineate, and differential considerations includes exophytic hepatoblastoma, renal and suprarenal masses, and retroperitoneal neoplasms.[236]

Solid Pseudopapillary Neoplasms

Solid pseudopapillary neoplasms of the pancreas (also known as *solid* and *papillary epithelial neoplasms*)[237] are a rare primary pediatric pancreatic tumor. In contrast to other pancreatic tumors occurring in children, however, the prognosis after complete surgical resection is favorable.[238] Studies have reported up to a 90% survival rate after complete resection. In one small study, median age at presentation was 13 years, with abdominal pain, a palpable mass, dyspepsia, and pancreatitis the most common presenting symptoms.[238] On imaging, usually by ultrasound and/or CT, solid pseudopapillary tumors appear as solid, well-demarcated masses. On ultrasound there is heterogeneous echotexture, occasionally with fluid-filled cystic spaces (Fig. 66-62). CT shows a heterogeneous mass with peripheral contrast enhancement. Although these tumors are slow-growing tumors with low-grade malignant behavior, FDG uptake on PET imaging has been shown in solid papillary tumors of the pancreas.[239] FDG-PET scanning may therefore be of value in follow-up imaging to assess for recurrence. Despite

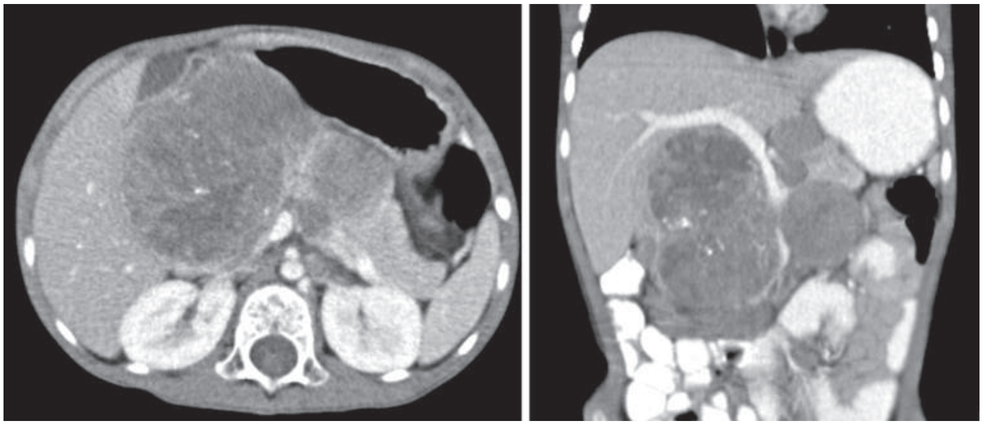

Figure 66-61 Pancreatoblastoma in a 4-year-old boy with a palpable abdominal mass. Contrast-enhanced CT shows a large, calcified retroperitoneal mass centered in the pancreas. Both adrenal glands were normal. Lung metastases were also present (not shown). The biopsy showed pancreatoblastoma.

high rates of overall 5-year survival, if metastases are present and not resectable, survival is poor with no clear, beneficial role reported for adjuvant chemotherapy or radiation therapy.[237]

Pancreatic Sarcomas

Mesenchymal tumors of the pancreas include rare synovial-cell sarcomas, myofibroblastic tumors, and metastatic rhabdomyosarcomas. Extremity rhabdomyosarcomas seem to have an unusual predilection for metastases to unusual cites such as the breast, ovary, testicle, and pancreas.[240] Two patients shown in Figure 66-63 had metastatic rhabdomyosarcoma to the pancreas. Local presentation may include pancreatitis and abdominal pain or may be incidental (see Fig. 66-48, *B*). A recent report from three major pediatric centers also noted an association of alveolar rhabdomyosarcoma with pancreatic metastasis,[241] emphasizing the importance of follow-up imaging in these patients and including an increasing role for routine FDG-PET/CT imaging to identify unusual sites of metastatic spread in patients with rhabdomyosarcoma.

Pancreatic Lymphomas

Burkitt lymphoma is well known to involve organs of the gastrointestinal tract, although isolated pancreatic involvement is unusual. Typically pancreatic involvement is accompanied by other sites of visceral and mesenteric disease. Diffuse pancreatic infiltration in the setting of Burkitt lymphoma is shown in Figure 66-64 in a child who had symptoms of pancreatitis. On ultrasound the pancreas was diffusely enlarged and heterogeneous in echogenicity. CT scan showed diffuse pancreatic enlargement, poor enhancement, and a homogeneous low attenuation. As is common for the rapidly dividing Burkitt lymphoma, a prompt response to chemotherapy was observed, with near complete resolution of pancreatic abnormalities 10 days after onset of chemotherapy.

Pancreatic Islet-Cell Tumors

Functioning islet-cell tumors of the pancreas are rare but important clinically because of symptomatic endocrine abnormalities that result from constitutive secretion of hormones normally tightly regulated by the endocrine

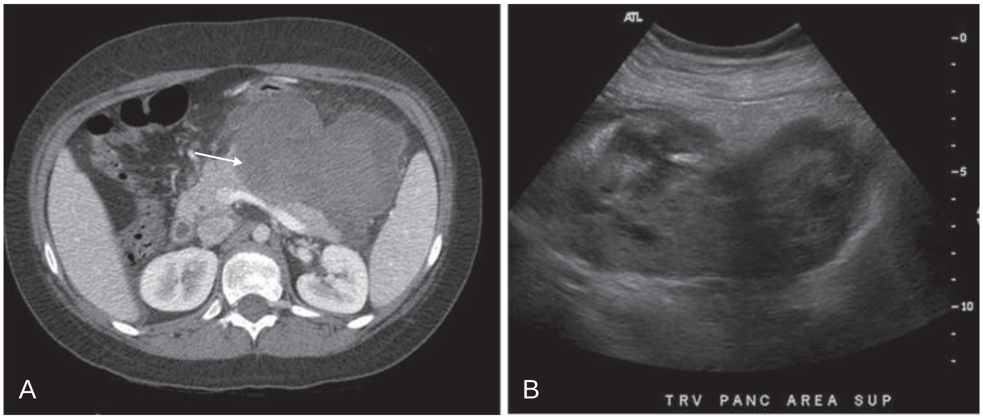

Figure 66-62 Pseudopapillary pancreatic tumor. This 9-year-old patient had hypertension and increased abdominal girth. **A**, CT shows a low attenuation, heterogeneously enhancing lobulated mass arising from the pancreatic body and tail *(arrow)*, which also abutted the greater curvature of the stomach (not shown). **B**, Ultrasound shows a lobulated solid mass that could not be distinguished from the pancreas.

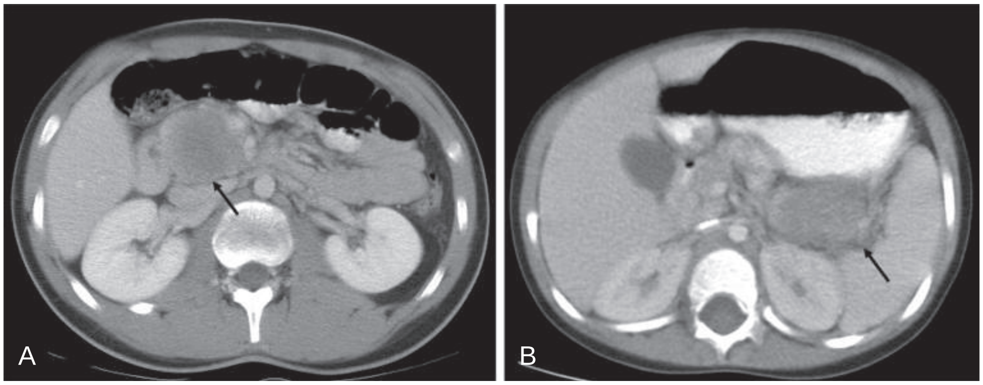

Figure 66-63 CT shows metastatic rhabdomyosarcoma to the pancreas in two patients with extremity rhabdomyosarcoma. **A**, The patient had symptoms of pain. **B**, The patient had no abdominal symptoms, and the lesion was detected by FDG-PET during routine surveillance.

pancreas. As shown in Figure 66-65, in which the patient had symptomatic hyperinsulinemic hypoglycemia, these tumors are often quite small and may be difficult to diagnose and characterize. As with other neuroendocrine neoplasms, optimal scanning techniques for detection of pancreatic islet-cell tumors include early arterial-phase scanning as part of a multiphase imaging technique. Thin sections (≈1 mm) are now routinely acquired by most multidetector-row CT scanners and the evaluation should include a careful review of sagittal and coronal reconstructed images. Although there are no controlled studies comparing CT and MRI in evaluating these tumors, a well-administered MRI examination with respiratory triggering/breath-holding, fast gradient-echo imaging, diffusion imaging, and dynamic-contrast administration is likely to yield comparable, if not superior results to CT. These small lesions are often difficult to see by conventional ultrasound; however, intraoperative ultrasound is invaluable for localizing small, nonpalpable lesions (see Fig. 66-65, *B*).

Alimentary Tract Tumors

Tumors of the gastrointestinal tract including the esophagus, stomach, and large and small bowel are rare in children. In the stomach, lymphomas, leiomyomas, lyomysarcomas, and adenocarcinomas are all rare as

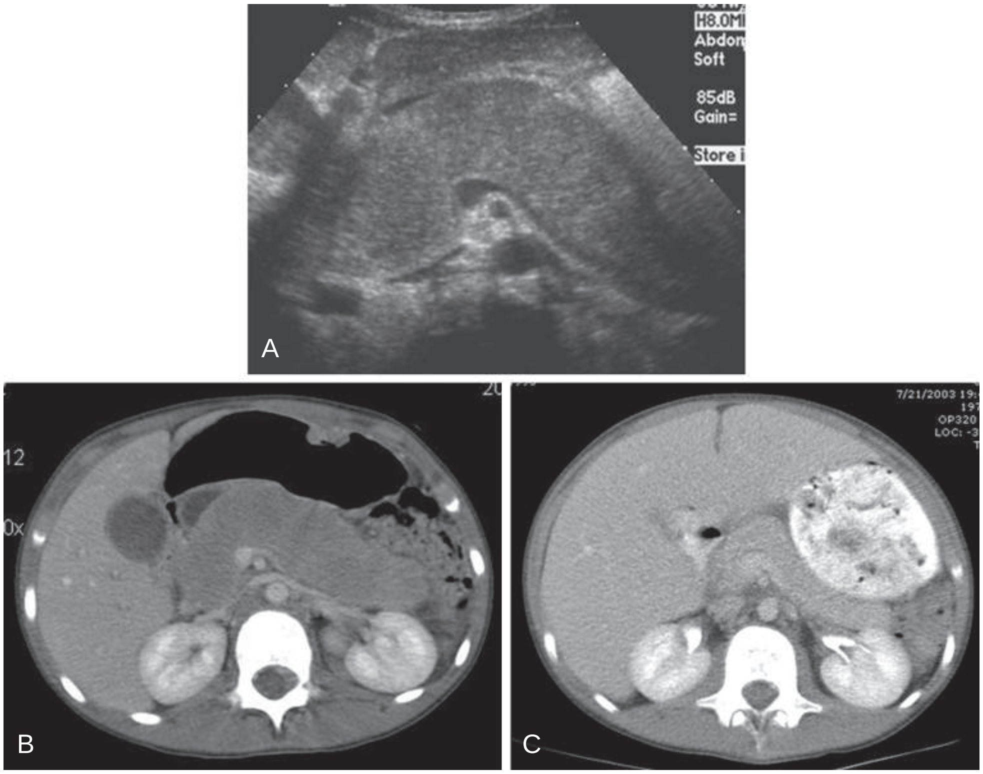

Figure 66-64 Burkitt lymphoma of the pancreas. An 8-year-old patient presented with pancreatitis. **A**, Ultrasound showed diffuse pancreatic infiltration, confirmed by CT (**B**), with disease limited to the pancreas. Ten days after initiating chemotherapy the pancreas appeared normal (**C**), typical of the rapid responses observed with Burkitt lymphoma.

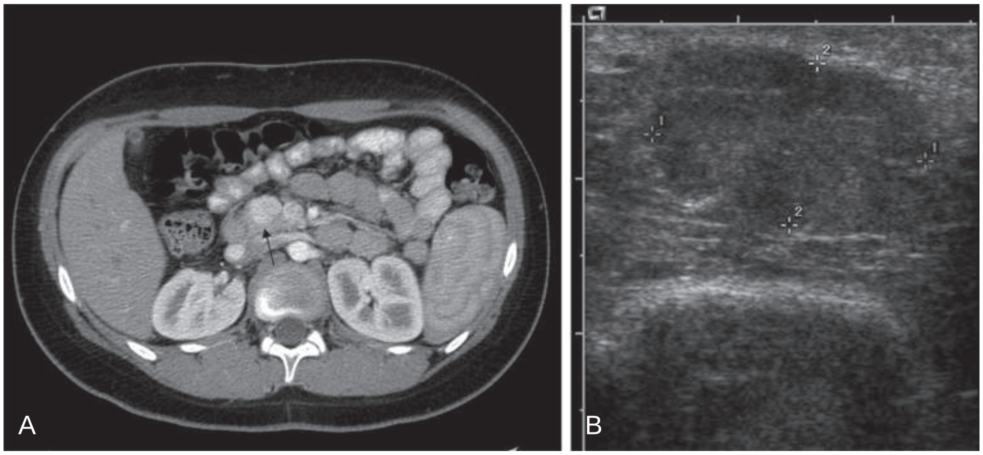

Figure 66-65 Pancreatic islet-cell tumor. This patient had profound hypoglycemia. **A**, CT shows a small enhancing lesion in the pancreatic head, adjacent to the superior mesenteric vein, detected only during the early arterial phase of scanning and consistent with insulinoma. **B**, Intraoperative ultrasound was essential to localize this small lesion before resection.

compared with adults. Gastrointestinal stromal tumors (GISTs) also have a low incidence in the pediatric population. Since early 2000, however, these tumors have attracted increased attention because of molecularly-targeted therapies (e.g., imatinib [Gleevec]) specifically inhibiting cell-surface receptors expressed on these cells. Although the majority of pediatric GISTs express a different cell-surface receptor mutation (*KIT* or *PDGFRA*)[242] and thus do not respond to imatinib like adult GISTs, the radiographic features are similar, with patients having a large mass closely apposed to the gastric wall. Depending on the size of the mass it may be difficult to distinguish between a pancreatic tumor invading the posterior gastric wall and a primary gastric tumor. On CT these tumors are often heterogeneous in attenuation with modest enhancement relative to the adjacent pancreatic tissue. For patients with localized disease, complete surgical resection is still the mainstay of treatment for this tumor, with targeted therapies being reserved for those patients with advanced or metastatic disease.[243] FDG-PET scanning has been shown to be important for staging and in follow-up evaluation, both as a measure of metabolic response to molecularly targeted therapy[243] and for early detection of small, local sites of relapse within the gastric wall that may be difficult to detect by conventional cross-sectional imaging techniques (Fig. 66-66).

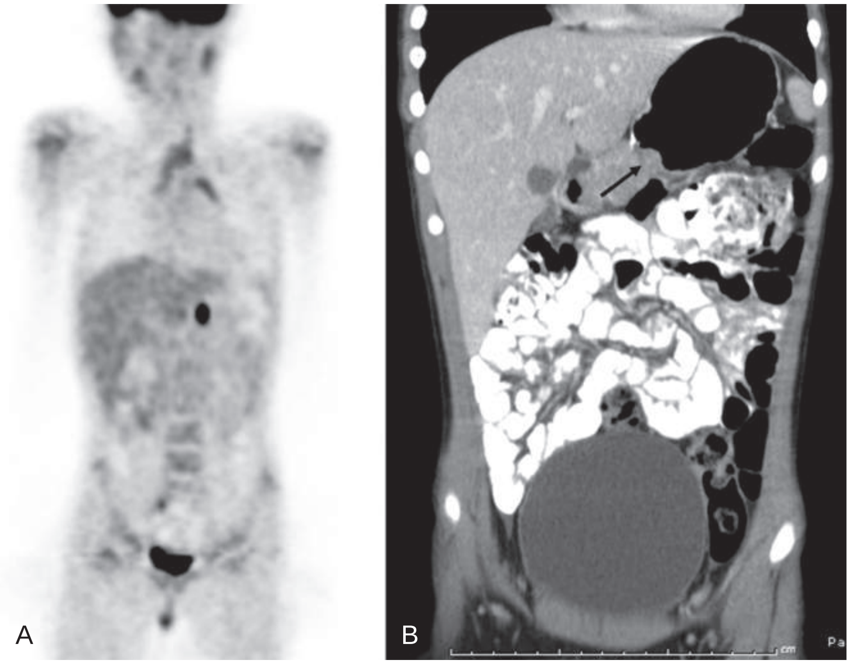

Figure 66-66 Images of a 9-year-old patient taken for routine follow-up examination after resection of a large GIST from the distal stomach. FDG-PET (**A**) shows intense focus of uptake in the upper abdomen, corresponding to a subtle nodular density seen by CT (**B**) along the greater curve of the stomach *(arrow)*. Endoscopic biopsy confirmed relapse at the resection margin.

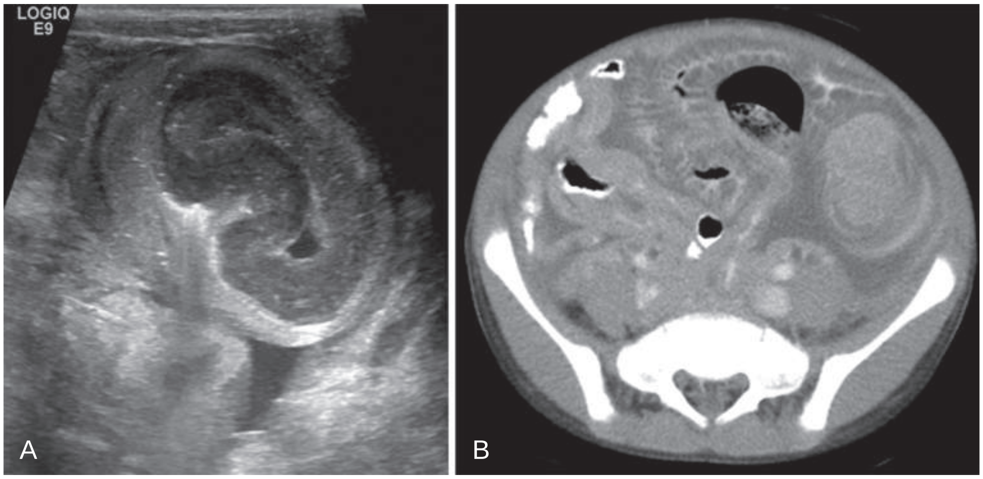

Figure 66-67 A 6-year-old patient with diffuse abdominal Burkitt lymphoma with symptoms of abdominal pain, diffuse bowel-wall thickening, adenopathy, ascites, and small-bowel intussusception, shown on both ultrasound (**A**) and CT (**B**).

The most common primary bowel malignancy in childhood is lymphoma. Small bowel is more often involved than large bowel, and this is most often non-Hodgkin lymphoma. Presentation is typically with abdominal pain, weight loss, anemia, gastrointestinal bleeding, or constipation. Intussusception or a palpable abdominal mass may bring the patient to attention sooner. In an older child (older than age 6 years) with intussusception, lymphoma should be the leading diagnostic consideration (Fig. 66-67). The majority of the small-bowel non-Hodgkin lymphomas are Burkitt lymphomas. These rapidly dividing tumors involve the bowel or small bowel/colonic mesentery and can become quite large and lead to intestinal obstruction. Burkitt lymphoma responds rapidly to chemotherapy and can be effectively treated with no residual imaging abnormalities seen.

The imaging evaluation may initially involve fluoroscopic/barium studies to assess nonspecific symptoms of abdominal pain. In the setting of suspected intussusception, conventional radiographs and ultrasound are usually sufficient to confirm the diagnosis. Attempts at hydrostatic or pneumatic enema reduction of intussusceptions occurring around pathologic lead points in the bowel because of lymphomatous infiltration of the bowel or mesentery should be undertaken with caution, because there is increased risk of perforation at the site of intussusception[244] and greater risk of failure at reducing the intussusception in these patients. Once the diagnosis of lymphoma has been made, a complete cross-sectional imaging (CT) staging examination, including the neck and chest, should be undertaken. Both intravenous and oral contrast are necessary for this evaluation. CT reveals bowel-wall thickening, mesenteric adenopathy, and often a large intraperitoneal/mesenteric mass. FDG-PET scanning has been shown to be effective in adult patients in staging and response assessment for non-Hodgkin lymphoma, and small case series have confirmed this finding in children, suggesting FDG-PET should probably be included in the diagnostic staging and posttreatment assessment of these patients.[245-248]

Adenocarcinomas of the colon and rectum are fortunately rare in children. As in adults, colonoscopy may provide the best early diagnosis for a suspected carcinomatous lesions. The staging evaluation for metastatic spread should involve imaging of the chest, abdomen, and pelvis, again with both intravenous and oral contrast. There is no clear role established for routine use of FDG-PET scanning in the staging of children with adenocarcinomas of the gastrointestinal tract.

Carcinoid tumors occurring in the gastrointestinal tract are rare and usually slow-growing but have malignant potential. The appendix is the most common location for carcinoid tumors. It is not uncommon for patients to show symptoms of acute appendicitis, with carcinoid tumors discovered at the time of appendectomy or incidentally during evaluation of the pathologic specimen.[249] When large, carcinoid tumors may also produce obstruction of the bowel or intussusception. Because of their propensity to metastasize to the liver, work-up should include imaging of the entire abdomen and pelvis with intravenous and oral contrast. Somatostatin receptor analogues (octreotide) are useful for occult sites of metastatic disease spread. These hepatic metastases are typically best demonstrated during the early arterial phase of contrast injection, which nicely delineates these hypervascular tumors relative to the surrounding hepatic parenchyma. Complete surgical resection remains the mainstay of therapy for disease localized to the appendix and is usually curative.[249]

GENITOURINARY TUMORS

Renal Masses

Wilms Tumors

Wilms tumors are the most common renal malignancy in children, representing 6% to 10% of all pediatric malignancies and making up greater than 80% of pediatric renal masses. The peak age of incidence is between 3 and 4 years, and bilateral disease is seen in between 5% and

TABLE 66-2 Childhood Wilms Tumor: National Wilms Tumor Study Group Staging[252]

Tumor Stage	Description
1	Tumor is limited to the kidney and is completely resected. The renal capsule is intact and tumor is not ruptured or biopsied before removal. No involvement of renal sinus vessels or evidence of the tumor at or beyond the margins of resection.
2	Tumor is completely resected, with no evidence of tumor at or beyond the margins of resection. Tumor extends beyond the kidney as evidenced by any one of the following: Regional extension of the tumor (i.e., penetration of the renal sinus capsule, or extensive invasion of the soft tissue of the renal sinus) Blood vessels within the nephrectomy specimen outside the renal parenchyma contain tumor.
3	Residual nonhematogenous intraabdominal tumor after surgery. Any one of the following may occur: Lymph nodes within the abdomen or pelvis are involved by tumor. Tumor implants are found on or penetrated through the peritoneal surface. Gross or microscopic tumor remains. Tumor is not completely resectable because of local infiltration. Tumor spillage occurs either before or during surgery, or tumor was biopsied before removal. Tumor is removed in more than one piece (e.g., tumor thrombus within the renal vein is removed separately from the nephrectomy specimen).
4	Hematogenous metastases (e.g., lung, liver, bone, brain) or lymph node metastases outside the abdominopelvic region are present.
5	Bilateral involvement by tumor is present at diagnosis.

10% of patients.[250,251] Wilms tumor is often associated with syndromes and nephroblastomatosis and typically presents as a painless, palpable abdominal mass. Occasionally, Wilms tumor is an incidental finding during a radiologic assessment for other indications such as trauma. Hypertension and hematuria only occur in about 25% of the cases.[250]

Tumor staging based on the NWTSG classification depends on surgical, pathological, and radiologic findings, and the imaging evaluation should be directed at determining spread to adjacent organs such as the pancreas, spleen, and liver and for intravascular extension into the renal vein, IVC, and right atrium (Table 66-2).[252] In addition, the imaging examination should assess for the presence of distant metastatic disease (lung and liver) and for the presence of contralateral kidney involvement.[251,253] Wilms tumor is a rapidly growing malignancy, and intraabdominal rupture at diagnosis, during chemotherapy, or at the time of surgical resection is a well-appreciated complication and a major risk factor for abdominal recurrence,[254] increasing the recurrence rate to as much as 20%.[255] Accurately identifying tumor rupture can be a challenge. In a recent review of 70 patients treated through the COG, preoperative CT imaging was found to have moderate specificity (88%) but relatively low sensitivity (62%) in the detection of Wilms tumor rupture, although ascites seen outside of the cul-de-sac, irrespective of fluid density, was most predictive of rupture.[256] When tumor rupture is identified, these patients are upstaged and treated as having stage 3 disease.[251,253]

The initial examination is often a conventional abdominal x-ray obtained for symptoms of abdominal pain or a palpable mass. The typical findings include displacement of bowel and a masslike opacity in the abdomen. An ultrasound should serve as the initial evaluation and usually confirms the renal origin of the suspected mass. Sonographically Wilms tumors are often quite large with relatively homogeneous echogenicity. There may be focal areas of hypoechogenicity or cystic change. Calcifications are uncommon. Ultrasound is also accurate and sensitive at detecting intravascular invasion, and both color and Doppler imaging are effective at establishing vascular patency (Fig. 66-68). Intravascular extension occurs in 4% to 10% of patients with Wilms tumor but is rare in neuroblastoma, helping to differentiate between these two tumors.[253] In a recent study evaluating the diagnostic performance of CT versus Doppler ultrasound in identifying intravascular extension of Wilms tumor, investigators from the COG found CT to be superior to ultrasound for detection of intravascular and cavoatrial thrombus.[257] Nonetheless because ultrasound is often the initial examination performed in these patients, early identification of intravascular extension into the right atrium is essential and may increase the sedation/anesthesia risk for a child for whom subsequent CT or MRI is planned.

Once the diagnosis has been suggested by ultrasound, further imaging of suspected Wilms tumor requires either CT or MRI to accurately stage the disease. Multidetector-row CT scanning allows for rapid scanning and in some instances may allow sedation to be avoided. High-resolution imaging techniques with multiplanar reconstructions are essential in determining the extent of tumor spillage, local invasion, invasion into vascular structures, and presence of pulmonary metastatic disease. Early studies suggested that pulmonary metastases detected only by CT should not result in upstaging of the patient, relying on the chest x-ray to identify pulmonary metastases.[253] Subsequent work by European investigators in the International Society of Paediatric Oncology (SIOP) and in North America with the NWTSG identified a small cohort of patients with pulmonary lesions visualized only by CT scanning in whom disease stage would be advanced based on the CT results.[253] One study showed an increased risk of relapse in patients with positive CT findings.[258] Others, however, reported either no difference in prognosis between patients with positive or negative chest CT scans[189,259] or improvement in event-free survival rates, but with no impact on the overall survival rate and with no benefit from whole-lung radiation for patients with CT-only pulmonary nodules.[191] These studies are limited by their retrospective nature, and it remains controversial whether patients would have benefited from increased therapy.[251,253] Furthermore other investigators

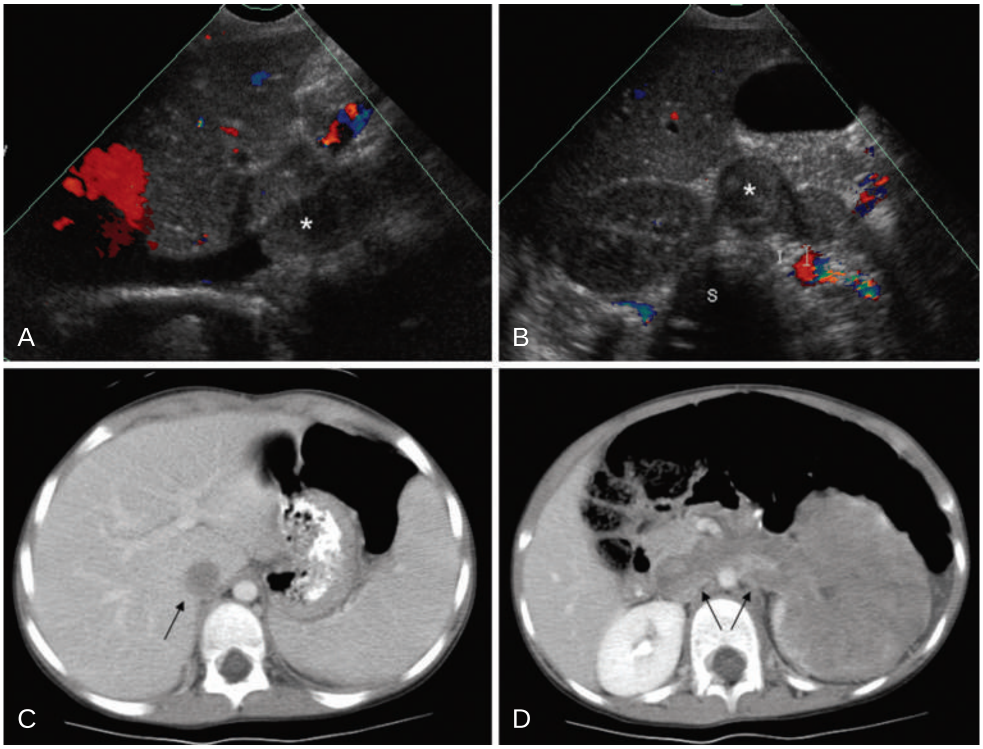

Figure 66-68 Wilms tumor. A 6-year-old child with a left renal Wilms tumor and left renal vein/IVC extension shown by ultrasound (**A** and **B**) and CT (**C** and **D**, *arrows*). Ultrasound confirms the complete absence of flow in the left renal vein and documents the level of intravascular invasion into the IVC *(asterisks)*. *s,* Spine.

have argued that CXR and CT data are concordant in the majority of cases,[190] and it as been shown that not all pulmonary lesions detected by CT represent metastases, even in the hands of experienced radiologists,[258] suggesting that surgical confirmation may be necessary to establish the malignant nature of suspicious lesions detected by CT in patients with Wilms tumor.[188] These considerations aside, it is current practice to obtain a chest CT for staging of all patients with Wilms tumor, with ongoing studies investigating the positive predictive value of this practice and its impact on overall clinical outcome.

Because of the need for chest CT in the staging evaluation, MRI is usually obtained for follow-up evaluation, either after resection or chemotherapy. In addition, MRI is the imaging modality of choice in monitoring nephrogenic rests that are seen in approximately 40% of patients with unilateral Wilms tumor and nearly all patients with bilateral Wilms tumors (Fig. 66-69).[260,261] Nephrogenic rests are remnants of primitive blastemal tissue that persist after birth and have the potential to transform into Wilms tumor. Nephroblastomatosis is the presence of multifocal or diffuse nephrogenic rests and is prevalent in patients with hemihypertrophy.[262] The distinction between nephrogenic rests and Wilms tumor may be difficult; however, there are certain distinguishing MRI features that may help discriminate between the two. On T1-weighted MRI images, Wilms tumors appear as well-defined heterogeneous masses with slightly lower signal intensity as compared with the adjacent renal cortex. On T2-weighted images Wilms tumors appear isointense to slightly hyperintense relative to the normal renal cortex. After intravenous gadolinium-contrast administration, Wilms tumors typically enhance heterogeneously but less than the surrounding renal parenchyma. Nephrogenic rests also exhibit decreased signal intensity on T1-weighted images, but in contrast to Wilms tumors maintain low signal on T2-weighted images.[263-265] Furthermore, nephrogenic rests show minimal enhancement after contrast infusion relative to the normal renal parenchyma, whereas foci of Wilms tumors show heterogeneous enhancement.[263,264] A role for FDG-PET imaging in the routine management of patients with Wilms tumor has not been established. However, studies documenting increased FDG accumulation in metabolically active Wilms tumors[266,267] suggest there may be role for FDG-PET imaging in Wilms tumor staging, posttherapy response evaluation, and possibly in helping discriminate benign nephrogenic rests from foci of transformed malignant tumor.

As discussed in the next section, the major differential considerations in patients with suspected unilateral Wilms tumor are clear-cell sarcoma of the kidney and rhabdoid tumor of the kidney, although there are no characteristic imaging features to make this distinction.

Clear-Cell Sarcomas

Clear-cell sarcomas of the kidney (also know as *bone-metastasizing renal tumor of childhood*) were previously thought to be a histologically aggressive variant of Wilms tumors. They occur less often than Wilms tumor (4% to 5% of pediatric renal neoplasms), with an estimated 20 new cases diagnosed annually in the United States.[268]

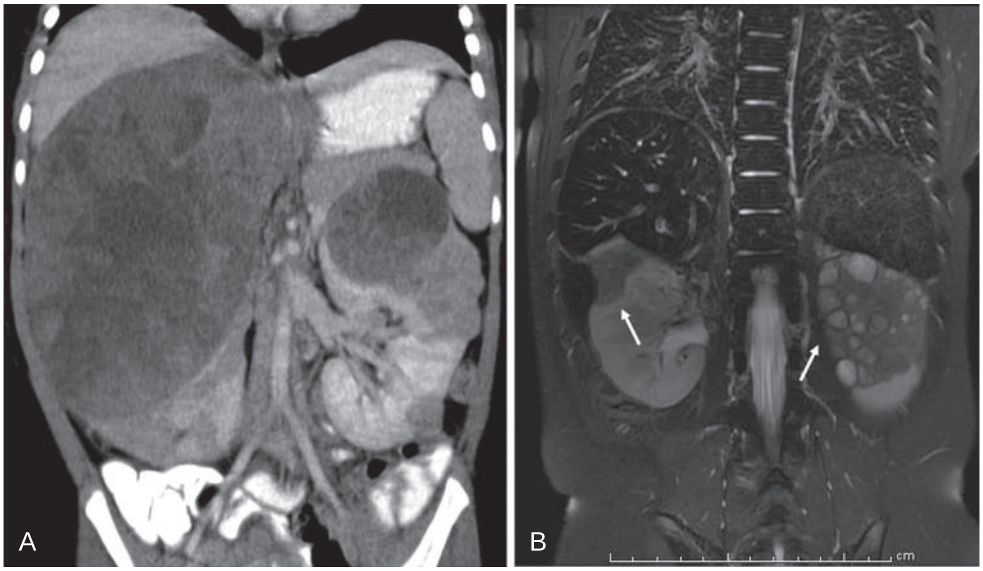

Figure 66-69 A 3-year-old patient with bilateral Wilms tumor, initially evaluated by CT (**A**). The patient underwent bilateral partial nephrectomies. **B**, MRI was used to monitor nephrogenic rests on both kidneys *(arrows)*, both for change in size and change in pattern of enhancement.

Although age at presentation ranges from infancy to the second decade, the peak incidence at about 2 to 3 years old closely parallels that of Wilms tumor, making differential diagnosis difficult. Bone metastases, which are unusual in Wilms tumor, occur commonly in patients with clear-cell sarcoma of the kidney and can have both osteolytic and osteoblastic activity.[250,262]

On imaging there are no specific features that allow distinction to be made from Wilms tumor.[269] Ultrasound confirms the renal origin of the mass, showing a heterogeneous mass with areas of hypoechogenicity and isoechogenicity reflecting cystic and solid elements within the mass. CT scanning is usually performed to more completely characterize the mass, assess for regional invasion, and check for metastatic disease. On CT, clear-cell sarcomas of the kidney are typically heterogeneous in attenuation with a variable pattern of contrast enhancement (Fig. 66-70). Vascular invasion is uncommon, and these tumors (in contrast to Wilms tumors) do not have a pseudocapsule and often infiltrate the adjacent renal parenchyma and perinephric spaces.[262] The most common site of metastatic spread is to locoregional lymph nodes, followed by metastases to the lung and bone.[270] Liver metastases also occur. As with Wilms tumor, the management of clear-cell carcinoma of the kidney involves a combination of nephrectomy and chemotherapy.[271] Clear-cell sarcomas are more aggressive than Wilms tumors with a higher relapse rate; the most common site of relapse is bone, and current recommendations include skeletal scintigraphy in follow-up screening examinations.

Rhabdoid Tumors of the Kidney

Rhabdoid tumors of the kidney are also extremely rare and are the most aggressive of the renal tumors in children. Previously thought to be a variant of Wilms tumor histology, they are now recognized as a discreet entity and account for approximately 2% to 3% of pediatric renal tumors. Rhabdoid tumors tend to occur in young infants, with more than 80% occurring in patients under the age of 2 years (Fig. 66-71).[272]

CT, ultrasound, and MRI all show a large heterogeneous intrarenal mass that often involves the central renal hilum. There may be associated vascular invasion, and calcifications may be seen. Although there are no distinctive imaging features to reliably distinguish rhabdoid tumor of the kidney from Wilms tumor (see Fig. 66-66), the findings of calcification, subcapsular hematoma, and a lobular, centrally located heterogeneous renal mass have been reported as characteristic imaging findings in patients with rhabdoid tumors of the kidney.[273] In addition, the association between rhabdoid tumors of the kidney and the presence of primary brain tumors (posterior fossa tumors, including medulloblastomas, PNETs, astrocytomas, and medulloblastomas) and synchronous or metachronous brain metastases are considered a unique and distinctive feature of this tumor.[272,274] Once the diagnosis of rhabdoid tumor of the kidney is established, therefore, the subsequent staging and follow-up evaluations should always include imaging of the brain to assess for intracranial disease.

Renal-Cell Carcinomas

As children enter their teenage years, the incidence of Wilms tumor decreases and the incidence of renal-cell carcinoma rises. Although there have been rare reports of renal-cell carcinoma occurring in infancy, the vast majority occur in children in late adolescence.[250,262] Syndromes associated with renal-cell carcinoma include von Hippel-Landau syndrome, tuberous sclerosis, and Beckwith-Wiedemann syndrome. In contrast to adults, in whom hematuria is a common presenting complaint, children with renal-cell carcinoma more often have vague abdominal pain and an abdominal mass.

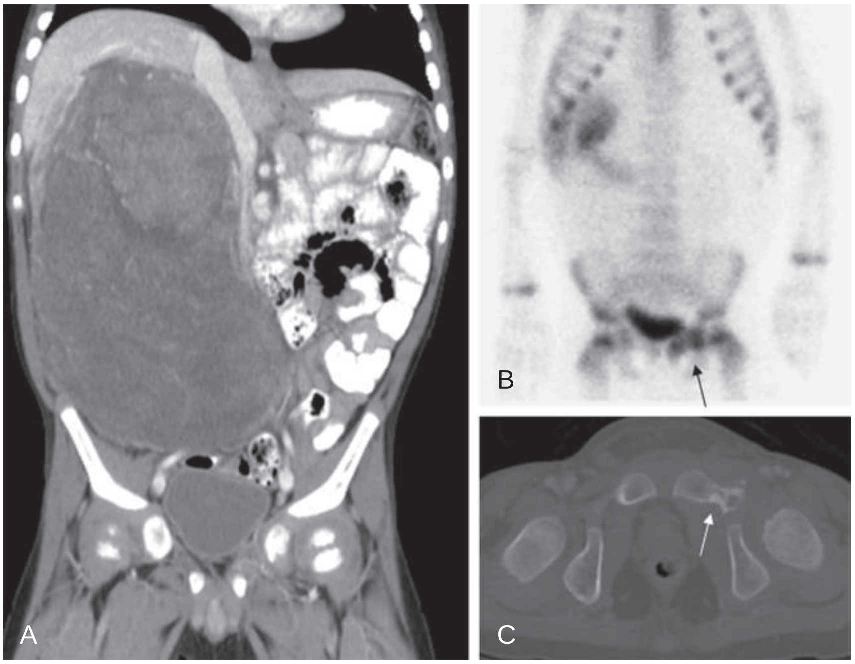

Figure 66-70 Clear-cell sarcoma of the kidney. A 2-year-old had symptoms of hip pain (x-rays were negative) and abdominal mass. Ultrasound (not shown) and CT (**A**) show heterogeneous masses with ill-defined margins, cystic and solid areas, and a variable pattern of contrast enhancement. Bone windows (**C**) revealed a destructive lesion in the left superior pubic ramus *(arrow)*, confirmed by bone scan (**B**), characteristic of the bone involvement seen with this renal neoplasm.

The imaging features of renal cell carcinoma and Wilms tumor overlap, although renal-cell carcinomas tend to show calcifications more often than Wilms tumors. Although renal cell carcinomas are more often bilateral and more commonly metastasize to bone than Wilms tumors, it is primarily the older age at presentation that favors renal-cell carcinoma over Wilms tumor. CT, MRI, and ultrasound all reveal a heterogeneous-appearing intrarenal mass. Multiple bilateral renal-cell carcinoma masses should suggest the diagnosis of von Hippel-Lindau syndrome.[272] Areas of cystic change may be seen, representing necrosis and hemorrhage, and calcifications are more common than in Wilms tumor (Fig. 66-72). After contrast infusion a heterogeneous pattern of contrast enhancement is seen on both CT and MRI. Local invasion into retroperitoneal lymph nodes and vascular invasion, particularly into the IVC, are common with renal-cell carcinoma and significantly influence the success of both primary surgical resection and overall prognosis. In some cases, when early-stage localized disease is established by CT and/or MRI, partial nephrectomy may be considered.[275,276] Intraoperative ultrasound can be valuable in guiding the surgeon and helping to define resection planes (Fig. 66-73). Because of increased incidence of bone metastases in renal-cell carcinoma, the staging evaluation should also include bone scintigraphy

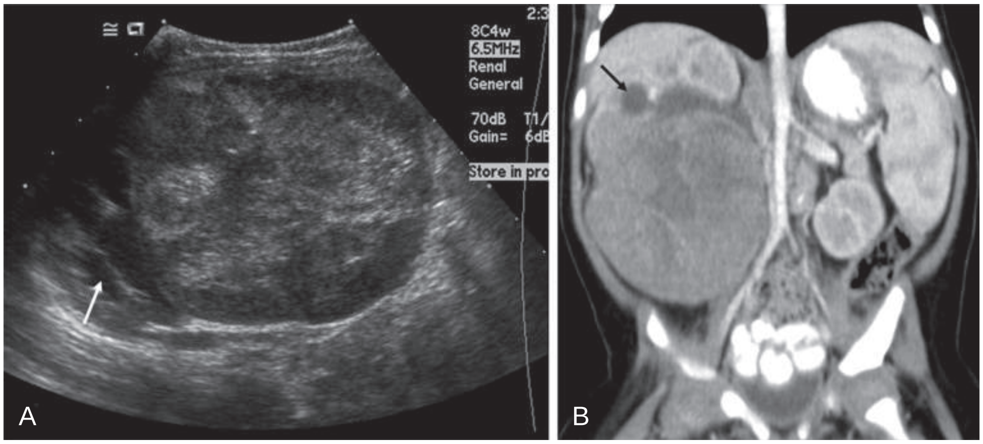

Figure 66-71 A 4-month-old patient with a palpable right renal mass. Ultrasound (**A**) and CT (**B**) show a centrally located lobulated mass causing obstruction of the right upper pole-collecting system *(arrows)*. On resection this was rhabdoid tumor. Note the difficulty in distinguishing this tumor from Wilms tumor (compare with Figs. 66-68 and 66-69).

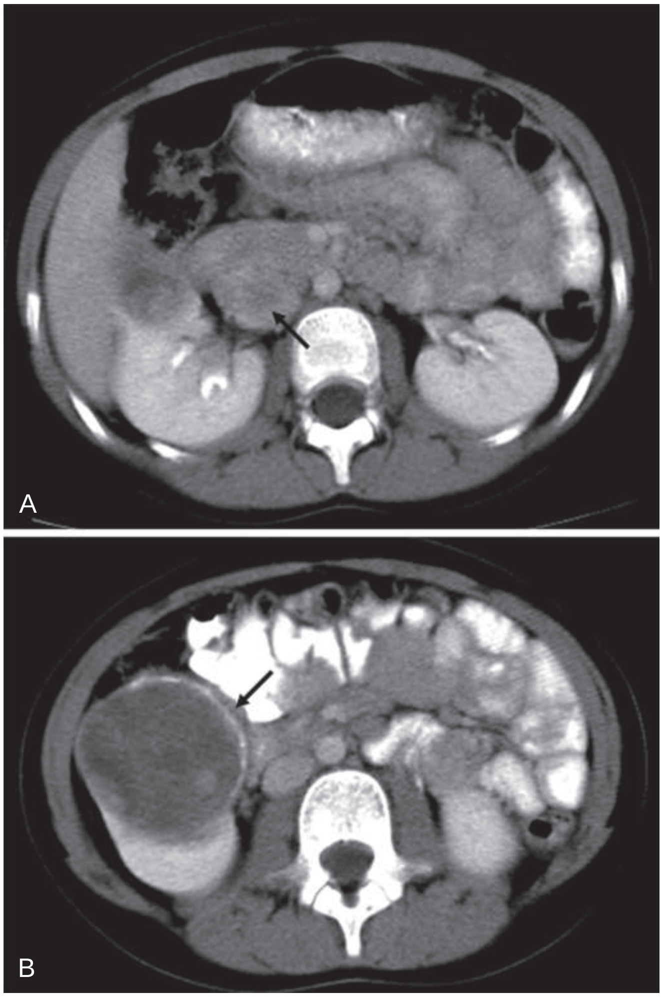

Figure 66-72 A 9-year-old child with a right renal mass that was found to be renal-cell carcinoma. Note the retroperitoneal lymph node spread (**A**, *arrow*), rim calcification (**B**, *arrow*), heterogeneous attenuation, and enhancement.

in addition to CT scanning of the chest, abdomen, and pelvis.

Congenital Mesoblastic Nephromas

Congenital mesoblastic nephromas, although not among the most common solid tumors in childhood, are the most common solid tumors of the neonatal period. They are benign tumor with almost three fourths of cases identified within the first year of life. With the advent of prenatal ultrasound screening, the incidence of early diagnosis is expected to increase. Infants typically have the presenting symptom of a large, palpable, abdominal mass. The imaging evaluation usually begins with ultrasound, showing a large, solid, renal mass that often involves the renal hilum (Fig. 66-74).[272] Although not a distinguishing feature, cystic elements are less commonly seen in mesoblastic nephroma than Wilms tumor. Congenital mesoblastic nephroma has been subdivided histologically into an aggressive high–cell-density variant and the classic variant, which has fewer active mitoses, less potential for local recurrence and metastasis, and overall better prognosis than the aggressive variant.[262,272] Hemorrhage, cysts, and necrosis, when present, are more often associated with the aggressive high–cell-density variant. Subsequent imaging by CT and/or MRI is usually performed to better characterize the intrarenal lesion and to assess for invasion into adjacent organs and structures (see Fig. 66-74). The imaging features alone do not allow distinction between mesoblastic nephroma and Wilms tumor,[270] and surgical resection is indicated. Because there may be poorly defined margins and the lack of a definable capsule, a surgical resection with wide margins is usually performed. The conventional benign histologic variant of this tumor is comprised primarily of benign connective tissue and mature mesenchymal cells, and prognosis is excellent if surgical resection is complete. Postoperative monitoring by ultrasound or MRI is still recommended, even with complete resection, for at least 1 year. With the aggressive cellular histologic variant, metastases and local spread of disease may require postoperative radiation and chemotherapy, and a more intensive follow-up imaging regimen should be directed at evaluating sites of local recurrence and typical metastatic spread (lungs, bone, and brain).[272]

Multilocular Cystic Nephromas

Multilocular cystic nephromas are benign renal tumors comprised almost entirely of coalescent cystic lesions with thin-walled septae.[277] Although the cystic appearance is distinctive, it is still not possible based on imaging features alone to discriminate between the cystic variant of Wilms tumor and the benign multilocular cystic nephroma. As with Wilms tumor, the typical age of presentation is between 2 and 5 years, with a smaller percentage occurring in young adults. Patients often have a large, painless, abdominal mass with no systemic symptoms.[272]

Radiographs may show a large abdominal mass displacing loops of bowel. The use of ultrasound is particularly important to demonstrate the cystic characteristics of these lesions, because CT scanning may simply show a large, low-attenuation mass with septations but not clearly demonstrate the hypoechoic cystic spaces revealed by ultrasound (Fig. 66-75). MRI shows characteristic fluid signal with low signal intensity on T1-weighted images and high signal intensity on T2-weighted images. After contrast enhancement, both by CT and MRI, enhancement of the thin-walled septae is seen, whereas the majority of the cystic mass remains unenhanced. Because the distinction between cystic Wilms tumor, clear-cell sarcoma, and multilocular cystic renal tumor cannot be made on the basis of imaging features, surgical resection is required for diagnosis.[270,271,277] Long-term prognosis is excellent; however; follow-up imaging is still necessary in the early stages postresection, because a low incidence of local recurrence is still possible.

Rare Renal Tumors

Two additional very rare tumors of infancy are the ossifying renal tumor of infancy and desmoplastic small round-cell tumors (Fig. 66-76). Both tumors characteristically calcify. Figure 66-76, *A* shows a renal hilar mass with

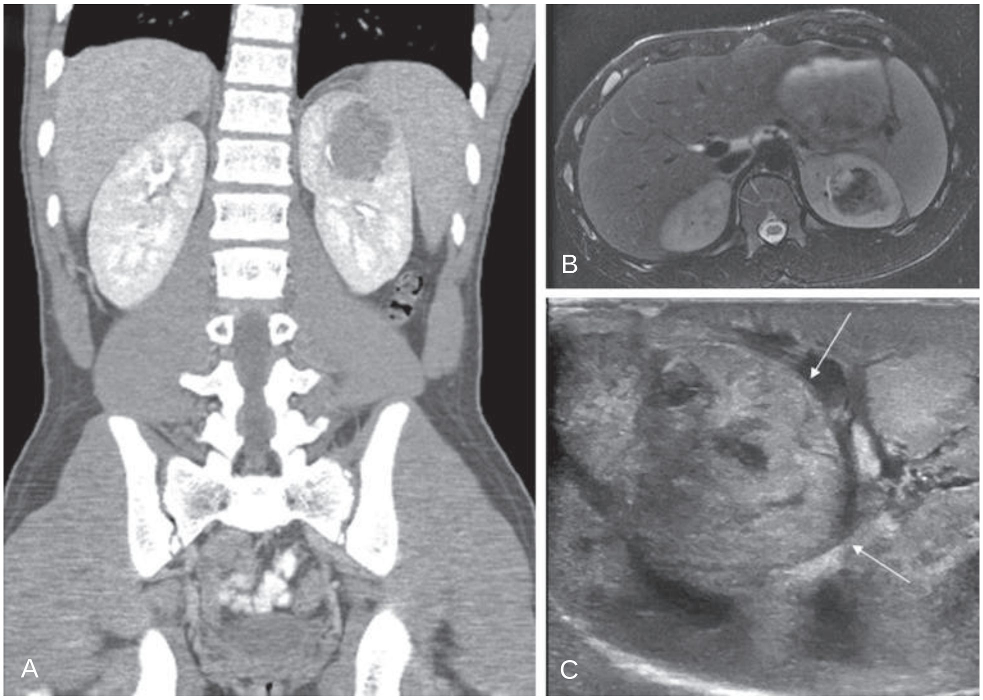

Figure 66-73 Renal-cell carcinoma in a 15-year-old patient with left flank pain and hematuria. Ultrasound showed left upper pole renal mass. CT (**A**) and MRI (**B**) show a low signal-intensity heterogeneously enhancing mass abutting the upper pole collecting system. Intraoperative ultrasound (**C**) defined a margin between the mass and renal parenchyma, vessels, and collecting system, allowing the patient to undergo partial nephrectomy of the upper pole.

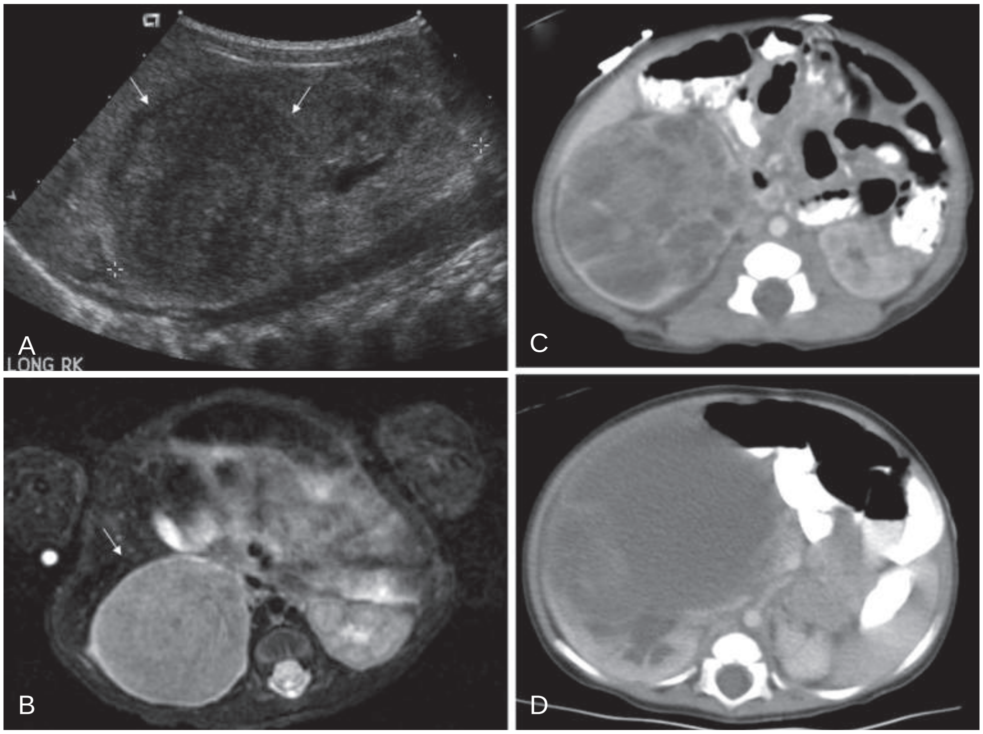

Figure 66-74 Congenital mesoblastic nephroma. **A** and **B** show a 7-day-old infant with a prenatally diagnosed solid right renal mass confirmed by ultrasound and MRI after birth. CTs from two other patients, newborn (**C**) and 5 months old (**D**), with large right renal masses showing both cystic and solid elements typical of congenital mesoblastic nephroma.

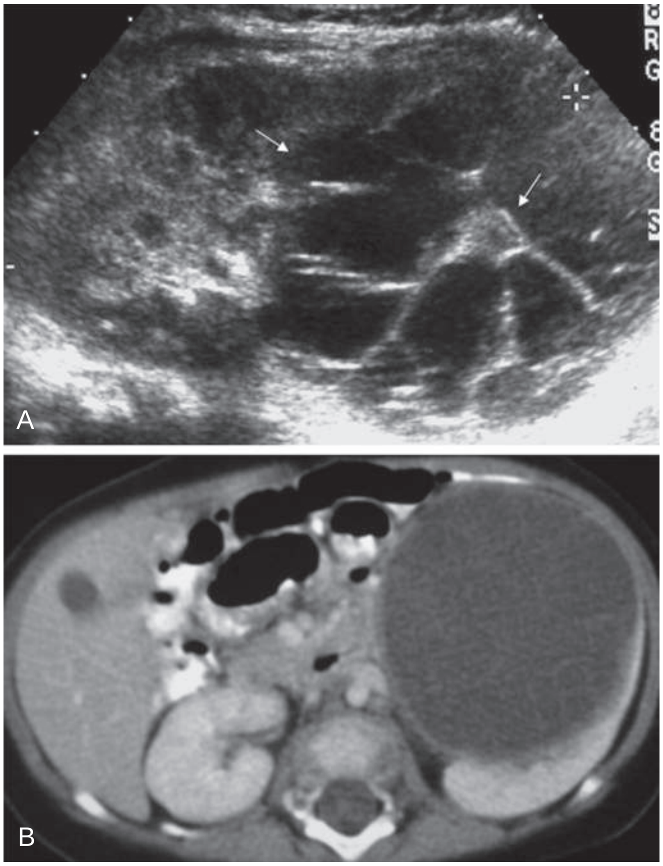

Figure 66-75 Multilocular cystic nephroma. Ultrasound shows a cystic left renal mass (**A**). Note how the cystic characteristics of these lesions and internal septations are not well demonstrated by CT (**B**), which simply shows a large low-attenuation mass, perhaps with thin internal septations.

extensive calcification that results from the ossifying renal tumors and is comprised of an osteoid core and osteoblastic tissue. Surgical resection is usually curative.[272] Desmoplastic small round-cell tumors are unusual as a primary renal neoplasm in children but have been reported.[278] As in other locations, these should be included in a differential for a calcified renal mass in a young child (see Fig. 66-76, *B*). Finally, metastatic disease to the kidney is unusual except in the settings of leukemia and lymphoma.[262] Leukemic involvement of the kidney typically manifests as diffuse nephromegaly. Lymphomatous involvement more often presents with discrete foci of lymphomatous infiltration and occurs in both non-Hodgkin and Hodgkin lymphoma subtypes. Burkitt lymphoma and T-lymphoblastic lymphoma are the non-Hodgkin lymphoma types most commonly presenting with renal involvement. This is probably the result of hematogenous metastasis, and in the setting of Burkitt lymphoma is usually associated with extensive mesenteric and retroperitoneal lymphadenopathy.[272] In the case of leukemia, diffuse nephromegaly may also be accompanied by hepatosplenomegaly; however, generalized adenopathy is less common. Ultrasound is usually sufficient to identify renal involvement by leukemia and lymphoma. Additional imaging by either CT or MRI confirms the diagnosis, demonstrating low-density lesions with little enhancement relative to the surrounding renal parenchyma (Fig. 66-77).

Bladder Neoplasms

In children, tumors involving the urinary bladder are uncommon, with rhabdomyosarcoma being the most common malignancy encountered. Adult-type tumors such as transitional-cell carcinoma, fibroepithelial polyps, and adenomatous lesions are unusual.

Rhabdomyosarcomas

Pelvic rhabdomyosarcomas arise from the bladder wall, prostate, and vagina. Tumors arising in the bladder and prostate often result in obstruction of urinary flow, symptoms of dysuria and hematuria, and urinary retention. Vaginal rhabdomyosarcomas present as pelvic masses with vaginal bleeding and occasionally prolapse of tumor from the vaginal orifice onto the perineum.[279]

Imaging evaluation is initially by ultrasound with rhabdomyosarcomas of the bladder presenting either as diffuse bladder-wall thickening or as polypoid or "botryoid soft-tissue masses" protruding from the bladder wall into the bladder lumen. Color and Doppler flow demonstrate increased vascularity of these lesions. Cystourethrography may be helpful to assess the degree of functional impairment and usually demonstrates filling

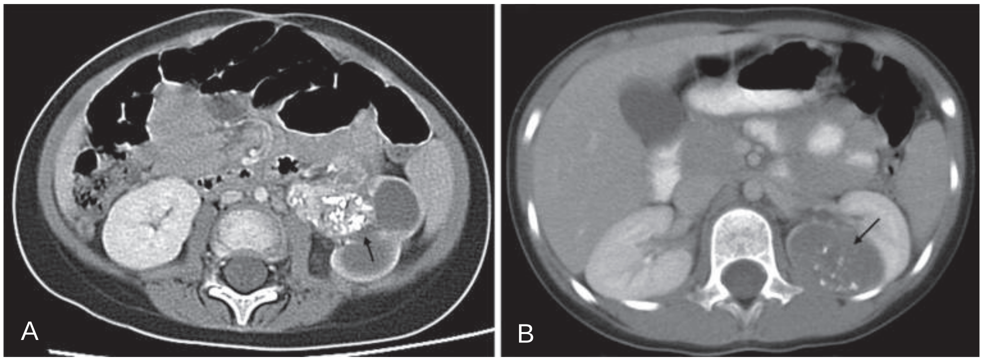

Figure 66-76 **A**, Ossifying renal tumor of infancy showing lobular renal hilar mass with extensive calcification *(arrow)* that results from the tumor being comprised of an osteoid core and osteoblastic tissue. **B**, Desmoplastic round-cell tumor of the kidney showing a well-circumscribed low-density mass in the left kidney with punctate calcifications *(arrow)* in a 6-year-old child who was being evaluated for hematuria.

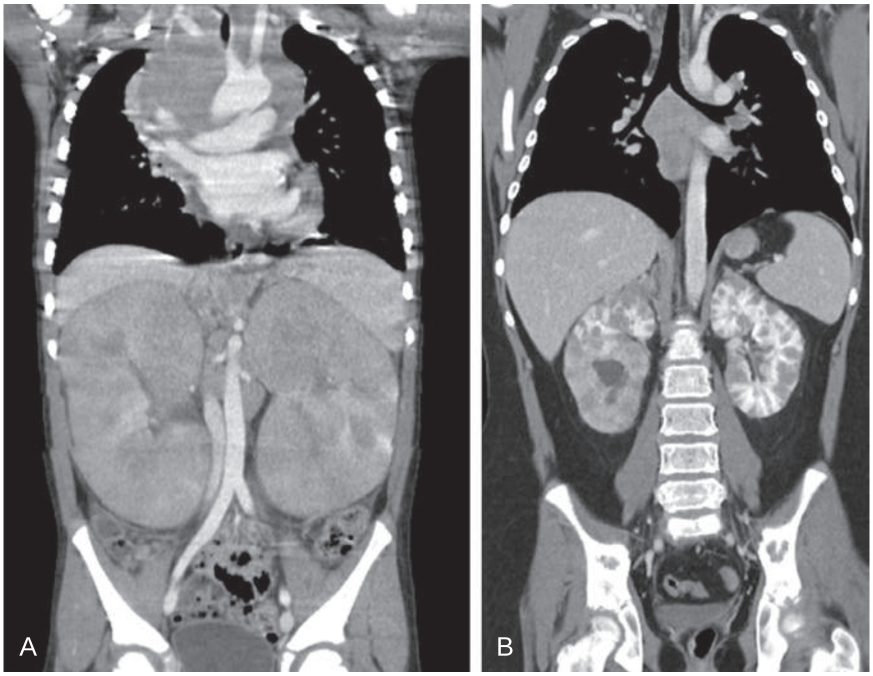

Figure 66-77 Renal involvement with leukemia and lymphoma. **A**, Diffuse renal enlargement and infiltration of the kidneys in a 6-year-old patient with T-cell lymphoblastic leukemia. This patient also had a large mediastinal mass at presentation. **B**, A 12-year-old patient with diffuse large B-cell lymphoma showing multifocal renal involvement as well as a mediastinal mass. Extensive bone involvement, seen under bone windows, is less evident here.

defects in the bladder, diminished bladder volume, and depending on the size and location of the lesion, obstruction to the flow of urine.

Contrast-enhanced CT scanning early after contrast infusion, after bladder filling, and after delayed bladder filling is helpful to assess the degree of local invasion. MRI, however, is preferable to characterize the lesion in multiple planes and to evaluate spread into adjacent pelvic organs and neurovascular structures.[280] Rhabdomyosarcomas typically show intermediate signal intensity on T1-weighted images with increased signal on T2-weighted images and heterogeneous or minimal enhancement on postcontrast images (Fig. 66-78). The imaging evaluation should be directed at assessing for local tumor extension into adjacent pelvic fat planes, adjacent lymph node enlargement, and involvement of the perivesical fat and adjacent musculature. Multiplanar fast-spin echo (FSE)–T2-weighted images with and without fat suppression are well-suited for detecting invasion of adjacent deep pelvic structures.

As with other rhabdomyosarcomas, metastases to the liver, bone, bone marrow, and lung occur, and the staging evaluation should include chest CT and bone scintigraphy. The role of FDG-PET in imaging rhabdomyosarcomas has not been the focus of any controlled prospective trials, but it has been observed[182,184,281] that rhabdomyosarcomas are usually FDG avid and that FDG-PET imaging can play in important role in identifying sites of occult disease, monitoring responses to therapy, and in evaluating equivocal foci of disease, either locally or at metastatic sites, that are identified by CT or MRI.[182]

ADRENAL/SUPRARENAL TUMORS

Neuroblastomas

Neuroblastomas are the most common non-CNS pediatric solid tumors and the third most common pediatric malignancy after leukemia and CNS tumors.[164,166] Greater than 90% of the cases occur in children younger than 5 years of age. Patients with neuroblastoma often have a painless abdominal mass. The most common site of origin is the retroperitoneum (adrenal gland), with other sites of origin in the posterior mediastinum, neck, and pelvis (at the level of the iliac bifurcation, the organ of Zuckerkandl).[164] Symptoms at presentation may also result from compression of adjacent organs, extension into the spinal canal, vascular compression/invasion, and bone involvement. Hypertension is seen in about 10% of patients and is caused by elevated catecholamine production. Paraneoplastic syndromes include the opsoclonus myoclonus syndrome and watery diarrhea. These symptoms commonly resolve after resection or chemotherapeutic treatment of the primary tumor.

The age and stage of disease remain the most important prognostic factors in neuroblastoma.[166] Infants (younger than 1 year of age) with localized disease have the highest rates of cure. Older patients with metastatic disease continue to be the most challenging population of patients to treat. The most widely-used staging system for neuroblastoma is the INSS (Table 66-3).[282,283] This involves a combination of radiographic, scintigraphic, surgical findings, and bone-marrow evaluation. Lower-stage disease is characterized by localized tumor involvement, whereas infiltration across the midline and/or

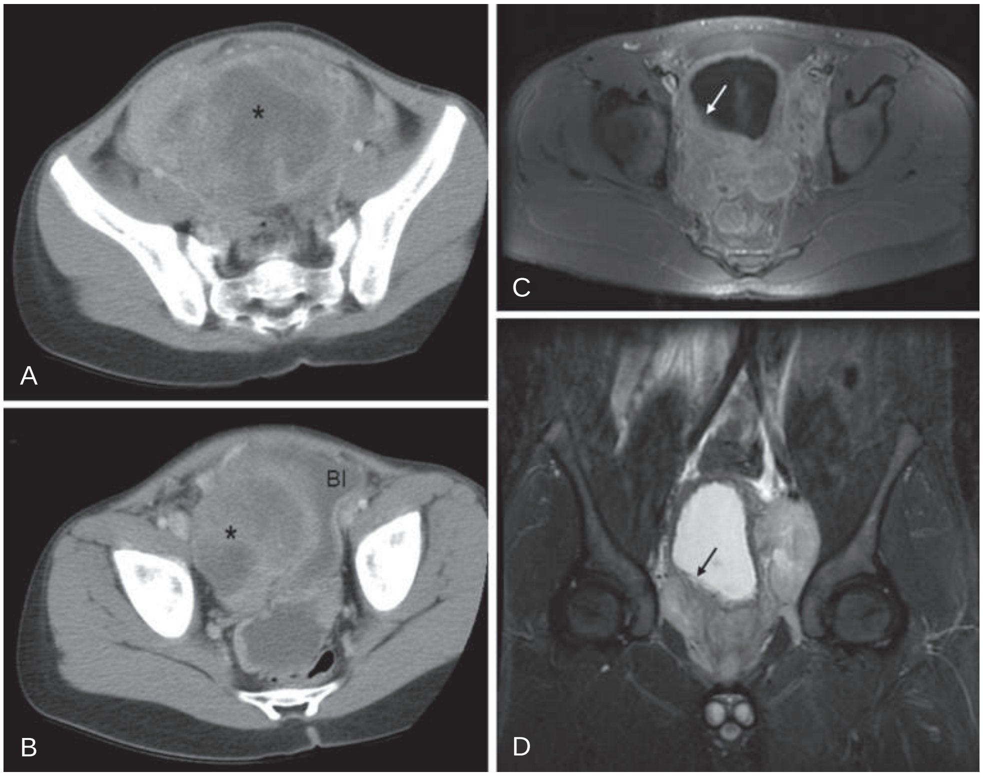

Figure 66-78 Rhabdomyosarcomas of the bladder and prostate. CT (**A** and **B**) shows large exophytic mass *(asterisk)* arising from the bladder wall and compressing the bladder lumen *(Bl)*. Contrast-enhanced (**C**) and FSEIR (**D**) MRI images show invasion of the bladder wall by prostatic rhabdomyosarcoma *(arrow)* showing the value of MRI over CT at demonstrating extent of invasion in the pelvis.

TABLE 66-3 Childhood Neuroblastoma: International Neuroblastoma Staging System[282,283]

Tumor Stage	Description
1	Localized tumor with complete gross excision with or without microscopic residual disease. Representative ipsilateral lymph nodes separate from the primary tumor are negative for tumor microscopically.
2A	Localized tumor with incomplete gross excision. Representative ipsilateral nonadherent lymph nodes are negative for tumor.
2B	Localized tumor with or without complete gross excision. Ipsilateral nonadherent lymph nodes are positive for tumor. Enlarged contralateral lymph nodes must be negative microscopically.
3	Unresectable unilateral tumor infiltrating across the midline, with or without regional lymph node involvement, or Localized unilateral tumor with contralateral regional lymph node involvement, or Midline tumor with bilateral extension by infiltration (unresectable) or by lymph node involvement. The midline is defined as the vertebral column.
4	Any primary tumor with dissemination to distant lymph nodes, bone, bone marrow, liver, skin, and/or other organs except as defined for stage 4S.
4S	Localized primary tumor as defined for stage 1, 2A, or 2B, and: Dissemination limited to skin, liver, and/or bone marrow. Limited to infants younger than 1 year. Minimal marrow involvement (i.e., <10% of total nucleated cells in aspirate). More extensive bone marrow involvement indicates stage 4 disease. MIBG scan should be negative for disease in the bone marrow.

MIBG, Metaiodobenzylguanidine.

encasement of major blood vessels that results in surgical unresectability define stage 3 disease. Widespread disease with cortical bone, bone marrow, or visceral organ involvement is defined as stage 4 disease. A unique feature to the staging of patients with neuroblastoma is the category stage 4S (special), which is defined as localized primary tumor with dissemination limited to liver, skin, and less than 10% bone-marrow involvement.[166] Because current approaches to risk classification and treatment stratification for children with neuroblastoma vary greatly throughout the world the International Neuroblastoma Risk Group (INRG) classification system has recently been proposed to establish a consensus approach for pretreatment risk stratification. Disease stage, age, histologic category, grade of tumor differentiation, the status of the *MYCN* oncogene, chromosome 11q status, and DNA ploidy were identified the most significant factors impacting clinical outcome.[284,285] New guidelines for staging and imaging of neuroblastoma have also been proposed as a result of the INRG recommendations, with recommendations for reporting two stages of localized disease based on whether image-defined risk factors (IDRFs) are present.[286] IDRFs are imaging findings based on preoperative imaging that are likely to impact surgical management, including success of gross total resection and risk of postoperative complications. A summary of the INRG imaging recommendations and IDRFs is shown in Table 66-4.

TABLE 66-4 International Neuroblastoma Risk Group Classification and Image-Defined Risk Factors

Descriptions of New International Neuroblastoma Risk Group Tumor Stages[286]	
Tumor Stage	**Description***
L1	Localized tumor not involving vital structures as defined by the list of IDRFs and confined to one body compartment.
L2	Local-regional tumor with presence of one or more IDRFs.
M	Distant metastatic disease (except stage MS tumor).
MS	Metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow.
Descriptions of IDRFs[†286]	
Anatomic Region	**Description**
Multiple body compartments	Ipsilateral tumor extension within two body compartments (i.e., neck and chest, chest and abdomen, or abdomen and pelvis).
Neck	Tumor encasing carotid artery, vertebral artery, and/or internal jugular vein. Tumor extending to skull base. Tumor compressing trachea.
Cervicothoracic junction	Tumor encasing brachial plexus roots. Tumor encasing subclavian vessels, vertebral artery, and/or carotid artery. Tumor compressing trachea.
Thorax	Tumor encasing aorta and/or major branches. Tumor compressing trachea and/or principal bronchi. Lower mediastinal tumor infiltrating costovertebral junction between T9 and T12 vertebral levels.
Thoracoabdominal junction	Tumor encasing aorta and/or vena cava.
Abdomen and pelvis	Tumor infiltrating porta hepatis and/or hepatoduodenal ligament. Tumor encasing branches of superior mesenteric artery at mesenteric root. Tumor encasing origin of celiac axis and/or origin of superior mesenteric artery. Tumor invading one or both renal pedicles. Tumor encasing aorta and/or vena cava. Tumor encasing iliac vessels. Pelvic tumor crossing sciatic notch.
Intraspinal tumor extension	Intraspinal tumor extension (any location), provided that more than one third of spinal canal in axial plane is invaded, the perimedullary leptomeningeal spaces are not visible, or the spinal cord signal intensity is abnormal.
Infiltration of adjacent organs and structures	Pericardium, diaphragm, kidney, liver, duodenopancreatic block, and mesentery.

From References 285 and 286.
IDRF, Image-defined risk factors.
*Complete definitions of these stages are cited in the text.
†Conditions that should be recorded but are not considered IDRFs are multifocal primary tumors, pleural effusion with or without malignant cells, and ascites with or without malignant cells.

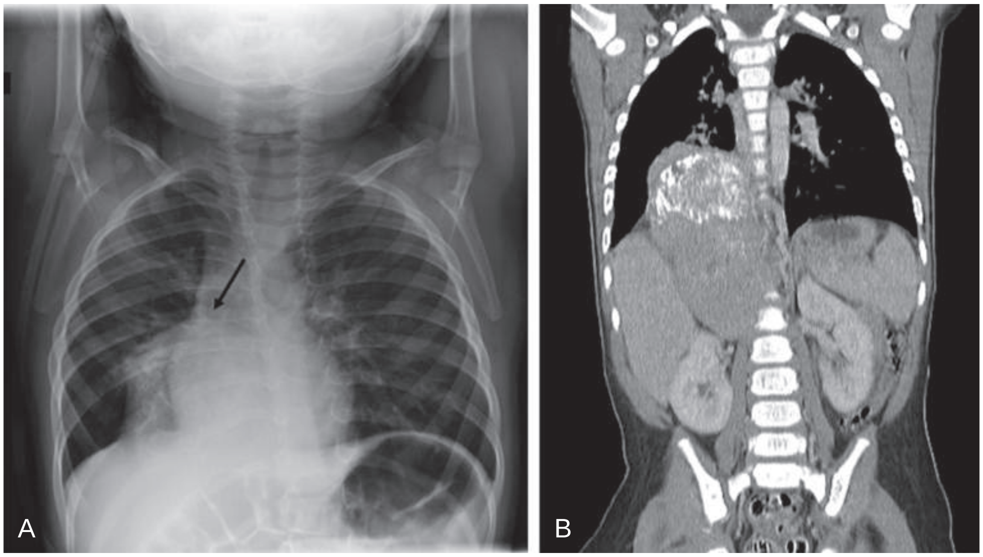

Figure 66-79 Neuroblastoma. **A**, Chest x-ray demonstrates calcified mass at the right lung base, seen on the lateral film to be posterior mediastinal (not shown). **B**, Coronal reconstructions from contrast-enhanced CT reveal a large, calcified right suprarenal mass with extension across the midline and into the thorax.

The initial imaging modalities used in evaluating patients with neuroblastoma are directed at the presenting symptoms. Abdominal films, chest radiographs, and skeletal films are usually obtained to assess abdominal distension, suspected pneumonia, or limp/extremity pain (see Figs 66-1 and 66-3; Fig. 66-79). Ultrasound is widely available and should be the first choice in evaluating a child with a suspected abdominal mass. Depending on the size of the mass, ultrasound can effectively demonstrate the presence of a retroperitoneal or suprarenal mass (Fig. 66-80) and is both sensitive and specific at evaluating for the presence of hepatic metastatic disease and localized vascular invasion. Calcifications are common in neuroblastoma and are seen sonographically as areas of acoustic shadowing. Depending on the age and size of the patient, intraspinal extension can also be detected.

CT scanning is widely used for defining the extent of primary tumor involvement and particularly with multiplanar reconstructions has become critical in the staging and surgical planning for patients with neuroblastoma (Fig. 66-81). The use of intravenous and oral contrast is essential in this evaluation, and scanning should include the chest, abdomen, and pelvis. The presence of intraspinal extension can often be detected by CT scanning; however, MRI is considered superior to CT in characterizing epidural extension or leptomeningeal spread of disease.[91] MRI, particularly with the advent of faster, whole-body scanning techniques together with diffusion weighted imaging, has also been advocated for use in determining extent of bone-marrow involvement.[167,287] In addition, MRI is effective in identifying unsuspected sites of bone and bone-marrow disease (Fig. 66-82), some of which may also be delineated by MIBG scintigraphy. MRI should also be considered for the monitoring of infants and children with low-risk disease, in whom treatment does not routinely involve radiotherapy and for whom reduction in radiation exposure is desirable. Guidelines for incorporating CT and MRI findings into the new INRG specifications for IDRFs have been published (see Table 66-4).[286]

The staging and monitoring of patients with neuroblastoma also depends on the use of scintigraphic studies, including bone scanning and MIBG scintigraphy. ^{99m}Tc-MDP scintigraphy has historically been used to detect the presence of cortical bone metastases and has been shown to be superior to conventional radiography,[91] although with current multimodality imaging and staging protocols, it is not clear that bone-scan findings impact the clinical stage of the majority of patient over the age of 1 year (see Fig. 66-77, C). MIBG is a catecholamine analogue taken up by neuroblastoma cells. ^{123}I-MIBG has been used to localize neuroblastoma at primary sites (Fig. 66-83), as well as in bone, bone marrow, and lymph nodes, and is effective in identifying sites of disease in more than 90% of the patients.[91,288] In particular, sites of previously unsuspected disease in the bone marrow are effectively detected by MIBG. Normal uptake by the liver, however, does limit the use of MIBG in detecting small foci of hepatic disease, and uptake by normal adrenal tissue after contralateral adrenalectomy may make postoperative follow-up observation challenging. Nonetheless, the relative sensitivity and specificity of MIBG for detecting disease not evident by other techniques has led most investigators to routinely include MIBG scintigraphy in the diagnostic and posttreatment evaluation of neuroblastoma patients.[289,290]

Although large controlled studies are lacking, a number of smaller consortium studies have shown that MIBG scanning at the time of staging has prognostic significance and that early response to therapy as detected by MIBG scintigraphy correlates with overall response and event-free survival.[291-295,296] As a result, MIBG scoring systems have been proposed to allow enumeration of the number

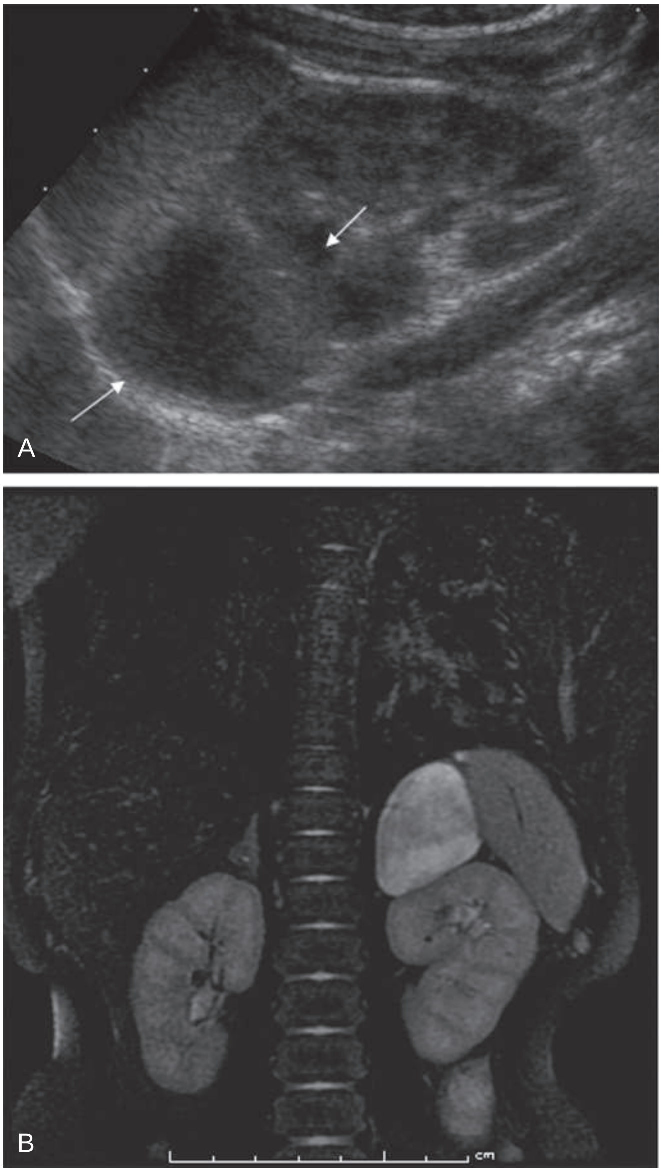

Figure 66-80 Neuroblastoma. Scans are of a 2-month-old infant being evaluated for vomiting. **A**, Ultrasound to assess for pyloric stenosis showed a well defined left suprarenal mass *(arrows)* confirmed by MRI (**B**).

of MIBG disease foci extent of MIBG avid disease, and have been used as a semi-quantitative means of monitoring responses to therapy, with good correlation with overall clinical response.[295,297,298]

FDG-PET imaging, although commonly used for many other tumor types, has not gained universal acceptance in the staging and follow-up evaluation of patients with neuroblastoma. PET scanning allows increased sensitivity and higher spatial resolution for disease detection.[70,299,300] However, discordant patterns of uptake,[169] combined with the general acceptance of MIBG scintigraphy and cross-sectional imaging for staging and response assessment, have resulted in the slow acceptance of FDG-PET in evaluation of patients with neuroblastoma.[91,169,301] Larger studies are needed to directly compare the sensitivity and specificity of FDG-PET with MIBG to determine the efficacy of FDG-PET imaging in the staging and post-treatment evaluation of patients with neuroblastoma.

Radiolabeled monoclonal antibodies, labeled with ^{131}I, ^{123}I, ^{99m}Tc, and ^{64}Cu, have all been used in both animal models and clinical models of neuroblastoma.[74,302,303] The antibodies upon which these imaging agents are based have mainly been directed against the disialoganglioside GD2, which has increased expression in neuroblastoma, and these same antibodies have been used clinically to treat patients with advanced stage disease.[304] However, the routine use of radioimmunodetection has still remained investigational in neuroblastoma patients.

Stage 4S neuroblastoma is unique among pediatric neoplasms. Identified in the early 1970s,[305] patients with this stage were identified as a "special" group with widespread neuroblastoma who had a favorable outcome. Criteria for defining these patients varied initially amongst cooperative groups. Currently, INSS stage 4S criteria include age younger than 1 year (increased to 18 months by the INRG) and localized primary tumor (not infiltrating across the midline and no contralateral lymph node involvement). Sites of metastatic involvement may include liver, skin, and bone marrow (less than 10% involvement). Patients with stage 4S disease comprise approximately 7% to 12% of all neuroblastoma cases, and despite extensive hepatic and primary site involvement, these tumors may completely resolve with observation alone and no additional chemotherapy (Fig. 66-84).

The importance of prenatal detection of neuroblastoma has also been emphasized recently in a study by Blackman, et al, in which a prenatal ultrasound and subsequent prenatal MRI delineated a large paraspinal mass.[306] In this case, the detection of spinal-cord compression by MRI combined with decreased fetal movement led to a rapid delivery, biopsy, further staging, and early initiation of treatment, which resulted in tumor response and preservation of lower-extremity neurologic function.

The opsoclonus myoclonus ataxia (OMA) syndrome is a paraneoplastic neurologic syndrome that has been associated with an occult neuroblastoma in up to 40% to 50% of patients.[307,308] Often the primary tumors associated with OMA syndrome are small, localized, and either paraspinal or extraabdominal. The identification of sites of disease is important, because symptoms may diminish or even resolve upon identification and treatment/resection of the neuroblastoma.[309,310] The imaging of patients with suspected OMA syndrome should include imaging of the chest, abdomen, and pelvis either by MRI or CT, as well as MIBG scintigraphy (Fig. 66-85).[91,311] MIBG scanning in particular has been shown to be both sensitive and specific for revealing occult neuroblastoma in patients with the OMA syndrome,[312] although with the availability of whole-body MRI, which affords a sensitive means of identifying sites of occult disease in a single examination, there is likely to be a shift in favor of whole-body MR screening for patients with OMA syndrome.

The distinction between neuroblastoma and its more differentiated counterparts ganglioneuroblastoma and ganglioneuroma cannot be made on the basis of imaging

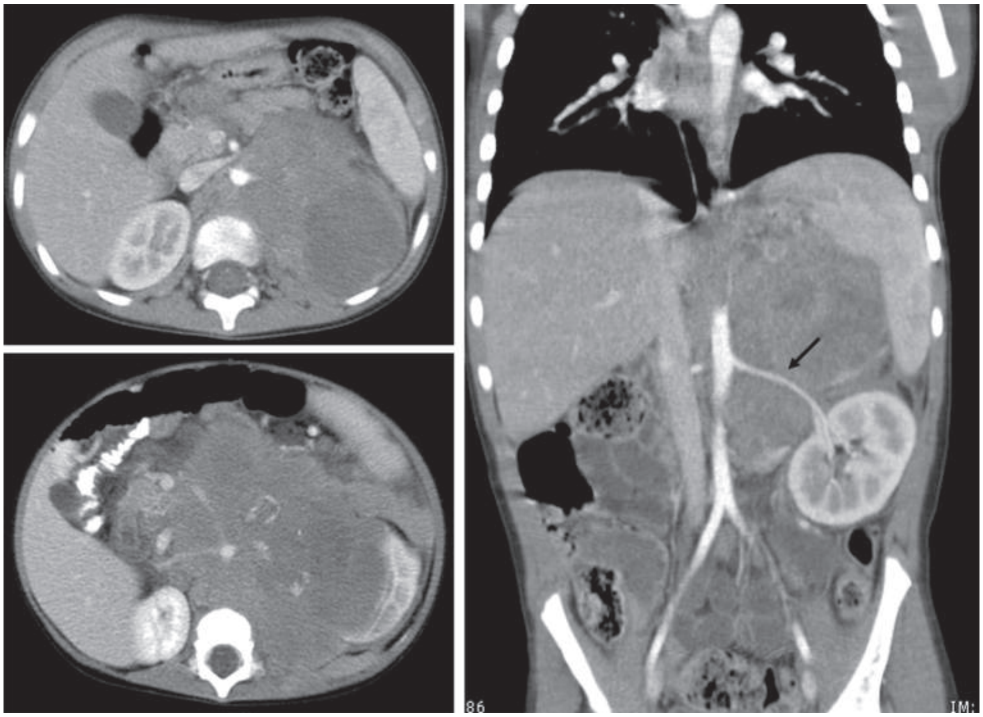

Figure 66-81 Neuroblastoma. Contrast-enhanced CT showing bulky retroperitoneal masses in two patients with encasement of vessels and extension across midline. Coronal reconstruction shows inferior displacement of the left kidney by the mass and demonstrate traction on the left renal artery *(arrow)*, which often leads to hypertension in such patients.

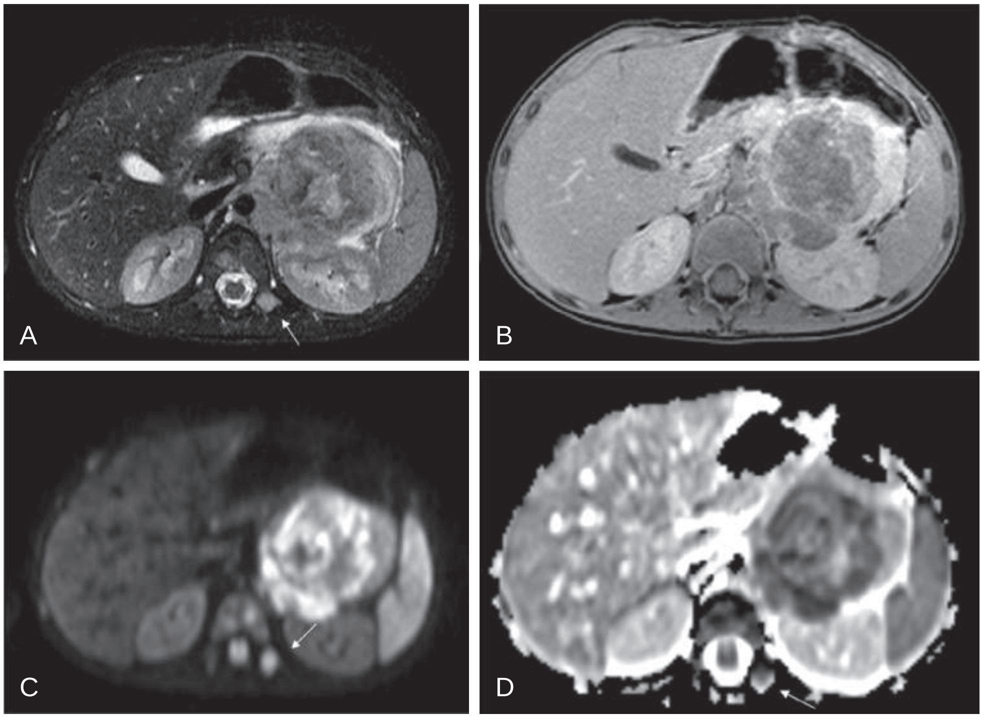

Figure 66-82 Stage 4 neuroblastoma. MRI shows left upper quadrant/retroperitoneal mass on T2-weighted (**A**) and post-Gd T1-weighted imaging (**B**). Diffusion-weighted imaging (**C**) and apparent diffusion coefficient (ADC) map (**D**) also reveal a focus of bone/bone-marrow involvement in the adjacent left vertebral pedicle *(arrow)* that is present but less conspicuous on the T2-weighted images and not seen on the post-Gd images.

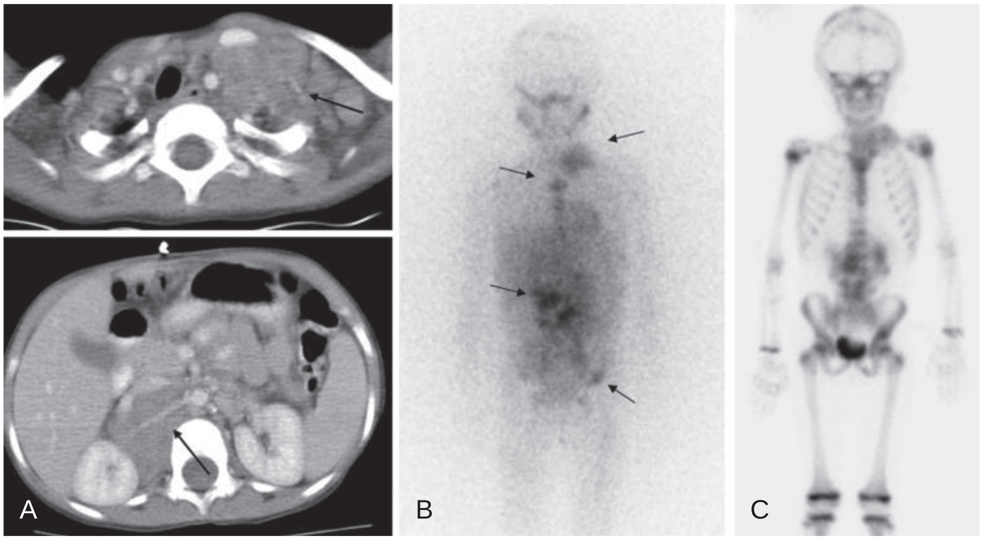

Figure 66-83 Neuroblastoma. Contrast enhanced CT (**A**) and MIBG (**B**) in a 5-year-old child showing intraabdominal, left supraclavicular, left acetabular, skull, and vertebral disease *(arrows)*. The thoracic vertebral disease is readily seen by MIBG but is not evident on CT. MDP bone scintigraphy (**C**) shows concordant uptake at most of these sites but does not reveal any additional sites of bone involvement; identifying additional sites would not have affected disease stage in this patient with stage 4 disease.

features alone.[164] Ganglioneuroma by definition shows completely differentiated stromal and cellular elements, with neuroblastoma containing less than 50% differentiated elements, and ganglioneuroblastoma intermediate between the two. Often patients who have responded to therapy will have residual lesions that remain MIBG avid and on biopsy are shown to be differentiated ganglioneuroma. In fact, novel treatment approaches are aimed at taking advantage of this potential for neuroblastoma to undergo differentiation, with cis-retinoic acid and its derivatives being used in an effort to accelerate the pathway toward differentiation.[313] Although biopsy/surgical resection is ultimately required to confirm the diagnosis, ganglioneuromas and ganglioneuroblastomas tend to be localized, with the most common sites of disease in the posterior mediastinum and retroperitoneum (Fig. 66-86). The age at presentation is also typically older than patients with neuroblastoma. Ganglioneuroma, like ganglioneuroblastoma and neuroblastoma, may accumulate MIBG, and MIBG uptake cannot be used to effectively discriminate between these distinct histopathologic entities.[314] Calcifications are often seen by CT and conventional radiography (see Fig. 66-86), and similar MRI appearances are seen with all three histopathologic types, with low signal intensity on T1-weighted images, intermediate to high signal intensity on T2-weighted images, and heterogeneous enhancement after gadolinium infusion. It is also important to recognize that sampling error can result after biopsy, and complete resection, if feasible, ensures a thorough sampling of the tumor specimen and a more confident diagnosis of ganglioneuroma.

Pheochromocytomas and Paragangliomas

Pheochromocytomas are rare pediatric tumors. They arise from chromaffin cells in the adrenal medulla or from cells of the extraadrenal sympathetic nervous system, where they are known as *paragangliomas*. In children these tumors are diagnosed from childhood to early adolescence, with a peak age range between 6 and 15 years. There is an increased incidence of pheochromocytoma in certain hereditary syndromes including the MEN syndromes IIA and IIB, von Hippel-Lindau disease, and neurofibromatosis type 1 (NF1). More recently pheochromocytoma/paraganglioma tumors have been associated with mutations in the succinate dehydrogenase gene family (*SDHB* and *SDHD*). The majority of these tumors (more than 80%) are located in the adrenal gland, with an increased likelihood of bilateral adrenal involvement in patients with MENII and von Hippel-Lindau disease.[315,316] Approximately 80% of patients have symptoms related to increased secretion of catecholamines, including sustained hypertension, headache, palpitations, anxiety, fatigue, and chest pain. Although these tumors are most often identified during the evaluation of clinical symptoms, they may also be discovered incidentally. The imaging features of pheochromocytoma are variable,[315] and while primary adrenal tumors are classically described on MRI as being hyperintense on T2-weighted images, low signal on T1 sequences, and showing a "salt and pepper" pattern of enhancement after contrast administration (Fig. 66-87),[315,317] these imaging characteristics are by no means specific for pheochromocytoma. ^{123}I-MIBG scintigraphy shows high specificity for pheochromocytoma and can be used to both identify lesions not seen by CT or MRI or to confirm the identity of abnormalities detected by cross-sectional imaging in patients with symptoms of catecholamine excess.[316,318] ^{18}F-dihydroxyphenylalanine (DOPA) PET and ^{18}F-fluorodopamine have both been shown to be superior to ^{123}I-MIBG, with greater sensitivity in detecting sites of metastatic disease,[319,320] although these agents are not in

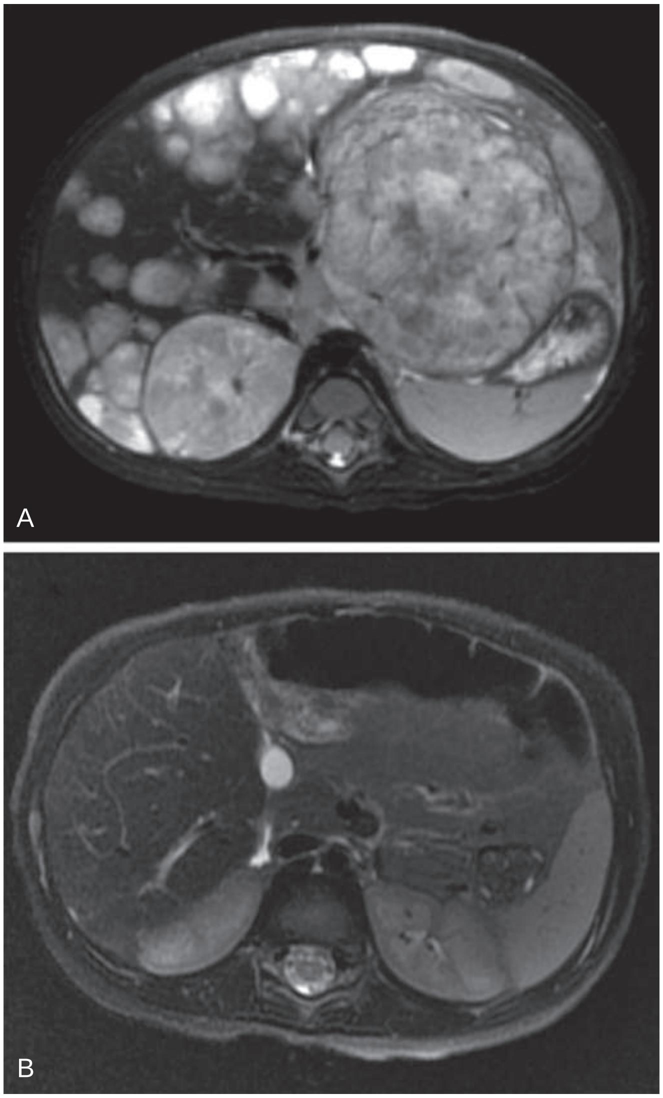

Figure 66-84 Stage 4S neuroblastoma. The patient is a 6-month-old baby with an abdominal mass. **A**, MRI shows extensive liver involvement. The infant was shown to have stage 4S disease. **B**, After 7 months of observation only and no chemotherapy, a repeat MRI shows near complete resolution of disease. This child continues with observation only.

routine use in the management of pediatric pheochromocytoma. Metastases are relatively uncommon in children (≈12%),[316] with the majority of patients having localized disease amenable to surgical resection. Higher rates of malignancy are seen in syndromic patients. Outcome is related to the presence and location of metastatic disease, with 5-year overall survival rates reported to be as high as 60% to 78% in patients with malignant metastatic tumors.[316]

GERM-CELL TUMORS

Gonadal and extragonadal germ-cell tumors are relatively rare in children, representing only about 1% of the tumors diagnosed in children under the age of 15 years. The most common extragonadal sites of disease in older children are the mediastinum and brain, and these tumors are discussed separately in those respective sections. Sacrococcygeal germ teratomas are the most common germ-cell tumors occurring in infancy and account for approximately 40% of all teratomas identified in children.

Ovarian Germ-Cell Tumors

Ovarian germ-cell tumors include both benign and malignant neoplasms.[279] The majority of the ovarian tumors are benign, with the most common tumor being the mature cystic teratoma/dermoid cyst. Malignant ovarian tumors include neoplasms of both stromal- and germ-cell origin, the former including Sertoli-Leydig cell tumors, granulosa thecal-cell tumors, and undifferentiated stromal tumors. Malignant ovarian tumors of germ-cell origin include dysgerminomas, immature teratomas, endodermal sinus tumors, embryonal carcinomas, and choriocarcinomas.

The imaging evaluation of malignant ovarian germ-cell tumors should be directed at characterizing the primary lesion and identifying possible sites of metastatic spread of disease. Ultrasound is usually the first imaging study performed to identify and characterize a suspected primary ovarian and/or pelvic mass.[321] Ultrasound reliably distinguishes between cystic and solid lesions and is helpful to assess blood flow to the lesion. The presence of associated ascites may also aid in the differential diagnosis. Additional evaluation by MRI and/or CT is typically performed as needed to further characterize the primary lesion and to assess for locoregional and metastatic spread of disease.

Sonographically the benign/mature cystic teratoma may be a homogeneous echogenic mass or alternatively a predominantly fluid-filled mass with an echogenic mural nodule. The presence of fat, calcification, or fat-fluid levels are all common findings in mature cystic teratoma (Fig. 66-88).[279] Large masses may be better characterized by CT and MRI, with CT scanning showing low-density lesions of fat density and heterogeneous enhancement of the solid components. Calcifications, particularly microcalcifications, are effectively identified by CT.

The MRI findings are variable depending on the characteristics and tissue composition of the teratomatous elements.[321] Typically mature teratomas have areas of both high and low signal on both T1- and T2-weighted images, with suppression of signal on fat-suppressed T1-weighted sequences. As shown in Figure 66-88, the presence of calcification, teeth, or hair may be useful in confirming the diagnosis. Even in the presence of mature elements, surgical resection is indicated, because the imaging features cannot clearly discriminate between malignant components of mixed germ-cell tumors and the entirely benign mature counterparts. The presence of lymph node involvement, extension into contiguous organs/structures, hematogenous spread, and evidence of peritoneal/omental seeding all should suggest the presence of malignant disease.[279]

It is important to correlate the imaging findings with the age of the patient. Functional ovarian neoplasms such

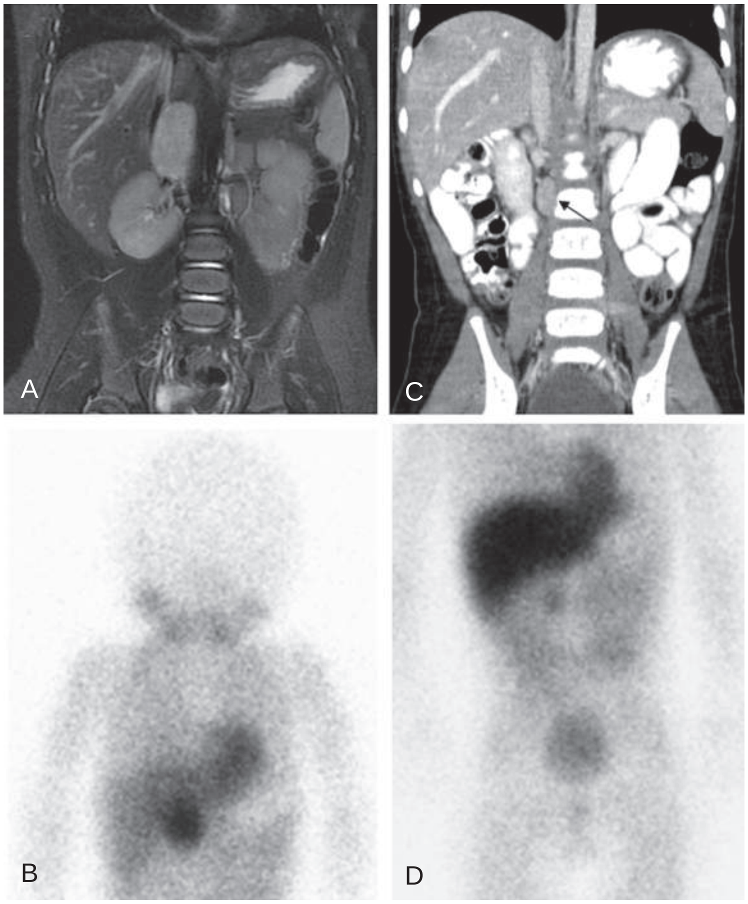

Figure 66-85 Two patients, ages 13 months (**A** and **B**) and 28 mo (**C** and **D**) with OMA syndrome secondary to occult neuroblastoma. MRI (**A**) and CT (**C**) show a right suprarenal mass (**A**) and subtle retroperitoneal lesion (**C**, *arrow*), both of which show focal MIBG uptake (**B** and **D**).

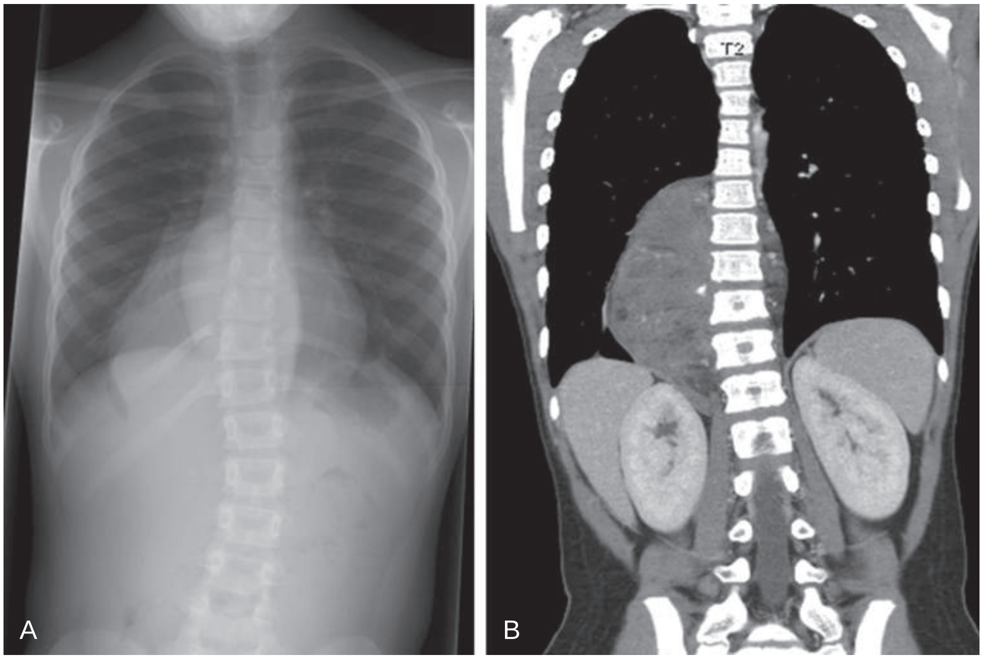

Figure 66-86 Ganglioneuroma in a 9-year-old child with back pain and scoliosis. Spine radiographs (**A**) and subsequent CT (**B**) showed a large paraspinal mass with calcifications also evident on CT. There was only faint MIBG uptake in the periphery of the mass (not shown), findings characteristic of mature ganglioneuroma.

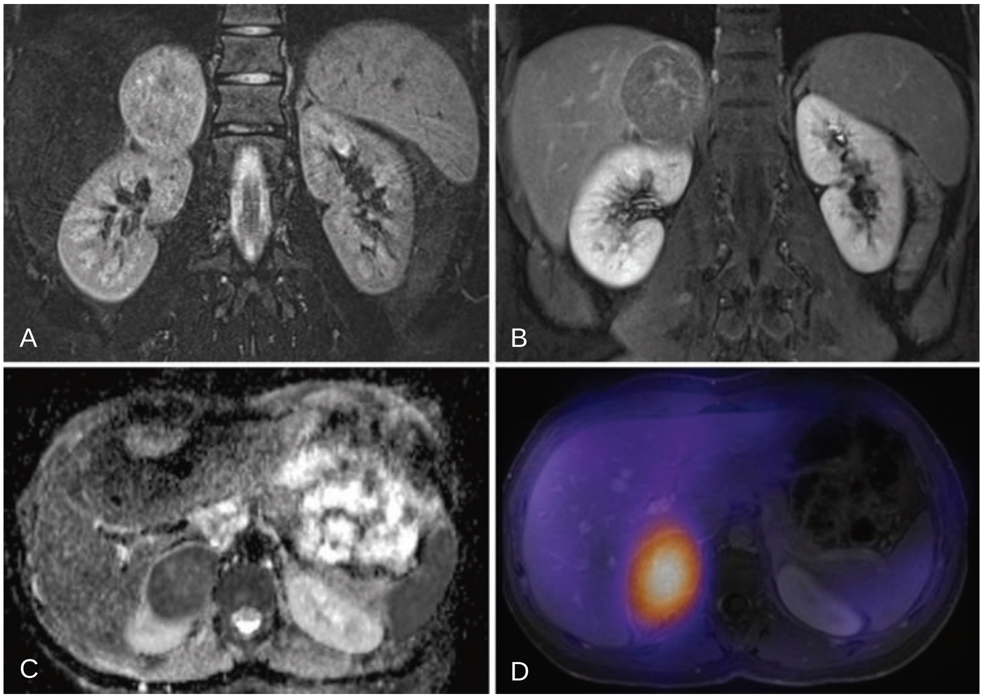

Figure 66-87 A 15-year-old patient with NF1 and an adrenal lesion detected on spine MRI. Coronal fat-suppressed T2-weighted (FSEIR) (**A**) and post-Gd fat-suppressed T1-weighted (**B**) images show a T2-bright lesion with a speckled ("salt & pepper") pattern of enhancement characteristic of pheochromocytoma. **C**, A DWI ADC map shows that the lesion has highly restricted diffusion. **D**, MIBG scintigraphy with SPECT images fused to the MRI show intense MIBG uptake in the lesion.

as granulosa thecal cell tumors may result in precocious puberty and sonographic findings that are discordant with the patient's age (Fig. 66-89). Correlation with serum hormone levels, AFP levels, and β human chorionic gonadotropin (HCG) levels is an important adjunct to the imaging evaluation.

The distinction between neoplastic masses of the ovary and nonneoplastic cysts, particularly hemorrhagic cysts, may be difficult. Nonneoplastic cysts are the most common etiologies for ovarian masses in infants and adolescent girls.[279,322] These hormonally responsive lesions arise as a result of follicular stimulation and corpus luteal maturation. Serial imaging by ultrasound is helpful in documenting stability and/or resolution of these benign processes and in making the distinction from their malignant neoplastic counterparts. Complex cysts and hemorrhagic cysts may be challenging to distinguish from solid neoplasms, and MRI with inclusion of fat suppression and magnetic susceptibility-weighted sequences can be helpful in discriminating fat-containing solid masses from complex hemorrhagic cysts.

Testicular Germ-Cell Tumors

Malignant testicular tumors are primarily of germ-cell origin, with the majority of these being malignant. The most common malignant testicular germ-cell tumor is the yolk sac, or endodermal sinus, tumor. Other malignant germ-cell tumors include embryonal carcinoma and teratocarcinoma. The benign teratomas seen more often in the ovary are less commonly encountered in the testes. Adult-type tumors such as seminomas and choriocarcinomas are less commonly encountered in infancy and begin to emerge around the time of puberty.[279]

Most testicular masses present with nontender scrotal swelling. Elevated serum AFP levels are common, and there is often spread to adjacent inguinal and retroperitoneal lymph nodes. The initial evaluation is usually by ultrasound to assess for the presence of a testicular mass and to distinguish between malignancy and nonneoplastic causes of scrotal swelling such as epididymorchitis, inguinal hernia or hydrocele, and testicular torsion. Sonographic features include an intratesticular mass with either increased or decreased echogenicity relative to the testicular parenchyma (Fig. 66-90). Color and Doppler assessments often reveal increased vascularity. The presence of an associated hydrocele, thickening of the spermatic cord, and extension of the mass through the tunica albuginea may indicate extratesticular spread of disease.[279] Once a mass has been confirmed, the staging evaluation should include imaging of the chest, abdomen, and pelvis to assess for regional lymph node spread and evidence of hematogenous disease spread, particularly to the liver and lungs.

FDG-PET imaging has been advocated in both the staging and follow-up evaluation of patients with malignant germ-cell tumors, with several studies showing the effectiveness of FDG-PET in identifying sites of disease that would otherwise have escaped detection on conventional cross-sectional imaging alone.[323-325] However, FDG-PET is unlikely to replace retroperitoneal lymph node sampling because of limitations in detecting small foci of disease.[326] In the only large prospective study

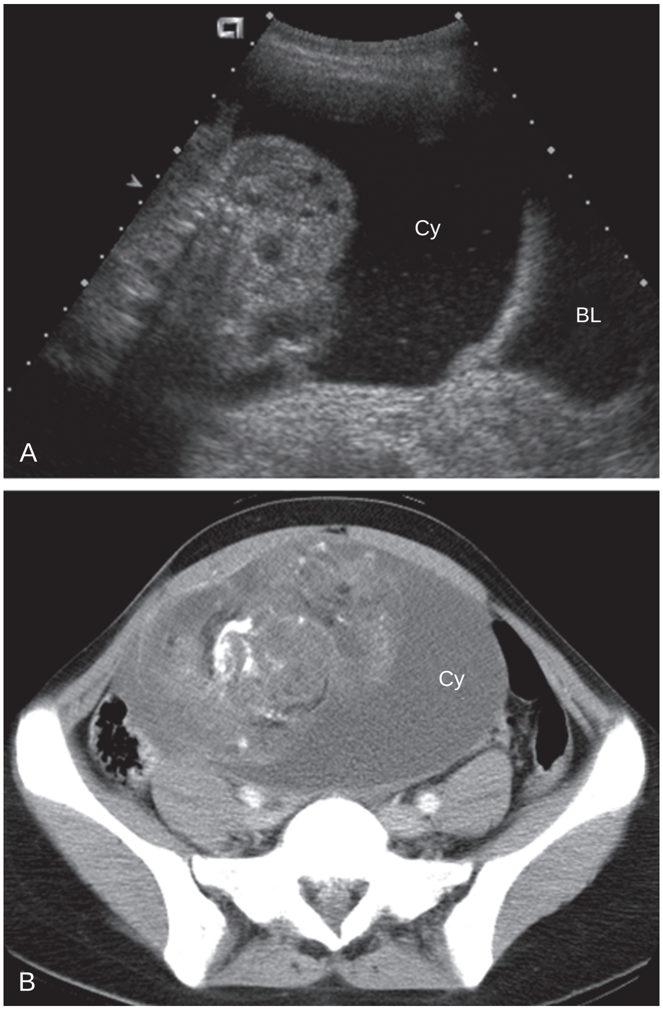

Figure 66-88 Mixed ovarian germ-cell tumor. Ultrasound shows a complex cystic and solid mass (**A**) that on CT showed areas of calcification within the solid mass (**B**), typical of germ-cell tumors.

available, posttherapy surveillance imaging with FDG-PET in patients with nonseminomatous germ-cell tumors did not confer a clinical benefit over CT and serum tumor markers for the prediction of tumor viability in residual masses.[327] Finally, there is a potential for false-negative findings on FDG-PET, particularly in the setting of mature, differentiated teratoma.[325]

Non–germ-cell tumors of the testes include Sertoli- and Leydig-cell tumors, both of stromal origin, as well as leukemia and lymphoma. Sertoli-cell tumors are more common in infancy, with Leydig-cell tumors occurring in early childhood and often accompanied by virilization or gynecomastia.

Sonographically, these testicular lesions are often heterogeneous and hypoechoic relative to the normal testicular parenchyma and usually demonstrate increased blood flow. MRI is not usually required to characterize the local site of disease; however, the MRI features of these testicular lesions include decreased signal intensity on T1-weighted images relative to the normal testicular parenchyma, increased T2 signal intensity, and heterogeneous enhancement. As with testicular germ-cell tumors, extension into the spermatic cord as well as inguinal and retroperitoneal lymph-node involvement, can be effectively demonstrated by MRI.

In children with cryptorchid testes, the presence of an undescended testicle is considered a predisposing factor leading to development of testicular tumors in childhood. Although the increased relative risk varies between published reports, there is little dispute that the risk of testicular cancer is increased in children and men with undescended testes.

Withdrawal of maternal estrogen at birth leads to a rise in testosterone and stimulation of testicular descent. Spontaneous descent of testes into the scrotum after 1 year of age is uncommon. The imaging evaluation of children with undescended testes should include a thorough ultrasound examination, with examination of the scrotum, inguinal canal regions, retroperitoneum, and kidneys. Often undescended testes can be located in the

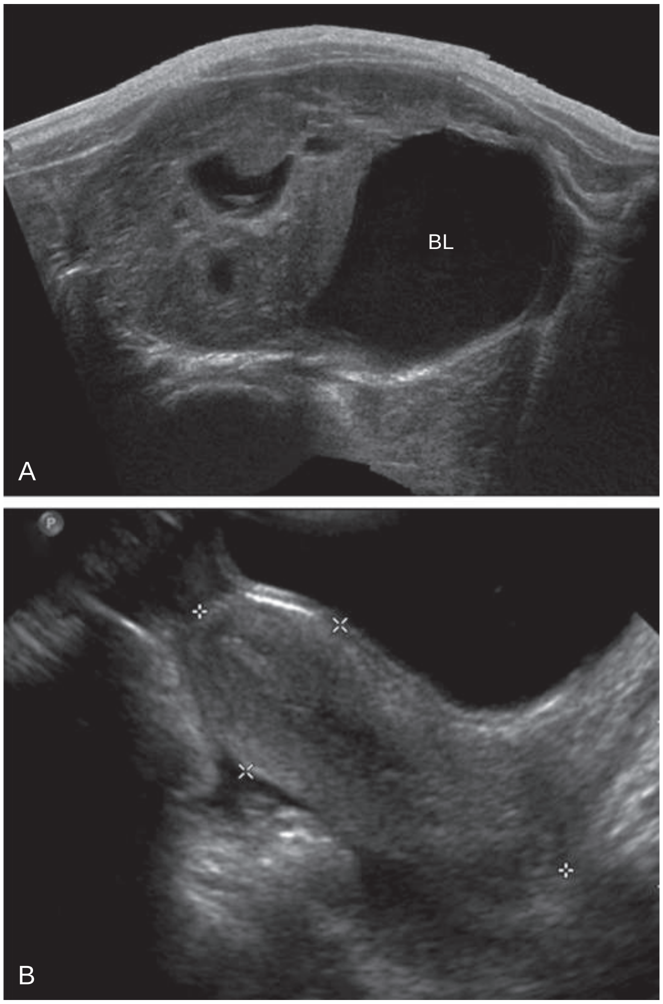

Figure 66-89 Granulosa-cell tumor. The images show a 5½-year-old child with the onset of menses. Luteinizing hormone/ follicle-stimulating hormone (LH/FSH): <0.1; estradiol: 144.5. Sagittal abdominal ultrasound image shows a mass adjacent to and above the bladder *(BL)* (**A**), likely arising from the left ovary. Note the post-pubertal appearance of the uterus (**B**), indicating a hormonally active mass.

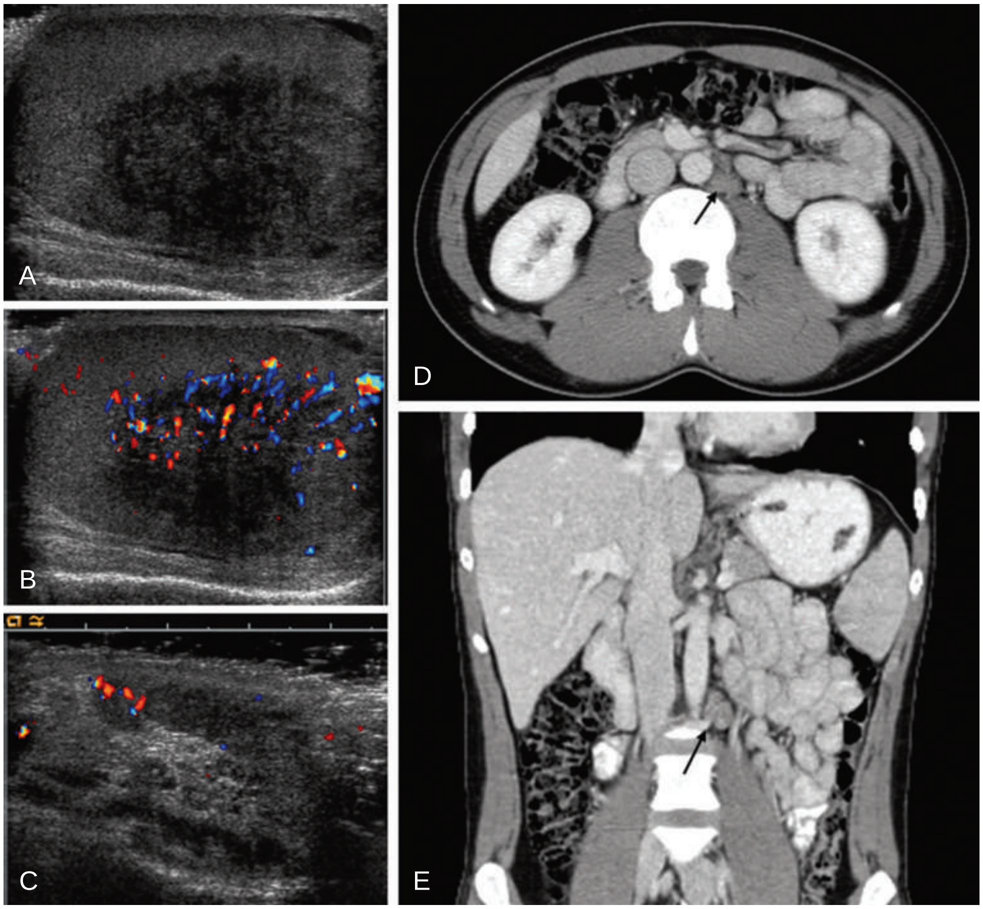

Figure 66-90 Testicular germ-cell tumor (embryonal carcinoma). Images show an 18-year-old patient with a palpable left-testicular mass. Ultrasound shows hypoechoic mass (**A**) with increased vascularity and thickening of the epididymis and spermatic cord (**B** and **C**). A small hydrocele was also present. CT shows an enlarged left retroperitoneal lymph node that is suspicious for extratesticular spread of disease (**D** and **E**, *arrows*).

inguinal canal and effectively relocated in the scrotum by orchidopexy. The retroperitoneal location of the undescended testes, although less common, is associated with a higher risk of malignancy as compared with those located in the inguinal canal. MRI may also be helpful in identifying undescended testes not detectable by ultrasound, particularly in older children where the homogeneously T2-bright testes can often be located along the expected pathway of descent of the developing testes.

Sacrococcygeal Germ-Cell Tumors

Sacrococcygeal germ-cell tumors are the most common germ-cell tumors in children. These germ-cell neoplasms include mature and immature teratomas and endodermal sinus tumors. Both mature and immature teratomas are considered benign, whereas mixed malignant germ-cell tumors indicate the presence of both benign teratomatous elements and malignant yolk sac tumor elements. Most sacrococcygeal teratomas are detected in the newborn period, whereas yolk sac tumors may be discovered later in childhood.[328] With the advent of prenatal sonography and prenatal MRI, an extensive prebirth evaluation of the tumor is often performed, facilitating a prompt surgical resection.

Sacrococcygeal teratomas are commonly classified according to the system of Altman[329] as type I, predominantly external with a very small presacral component; type II, predominantly external with a significant intrapelvic component; type III, predominantly internal with both pelvic and intraabdominal components; and type IV, entirely presacral without significant intraabdominal or external extension. The incidence of malignant elements is closely linked to the type of tumor, with almost 40% of type IV tumors having malignant components.[279]

In addition to the prenatal imaging evaluation, both CT and MRI can be used to effectively stage sacrococcygeal teratomas.[328] MRI is preferable in determining the extent of adjacent muscular, neurovascular, and intraabdominal invasion. MRI findings also reflect the heterogeneous nature of these tumors, with variable signal intensity on T1-weighted images, increased signal intensity on T2-weighted images, and heterogeneous enhancement after contrast administration (Fig. 66-91).[280] The presence of calcification, bone, and other more mature tissue elements may be better seen on CT. Metastatic disease to the lung, liver, and draining retroperitoneal lymph nodes can occur, and CT scanning of the chest and abdomen is an important component of the staging evaluation.

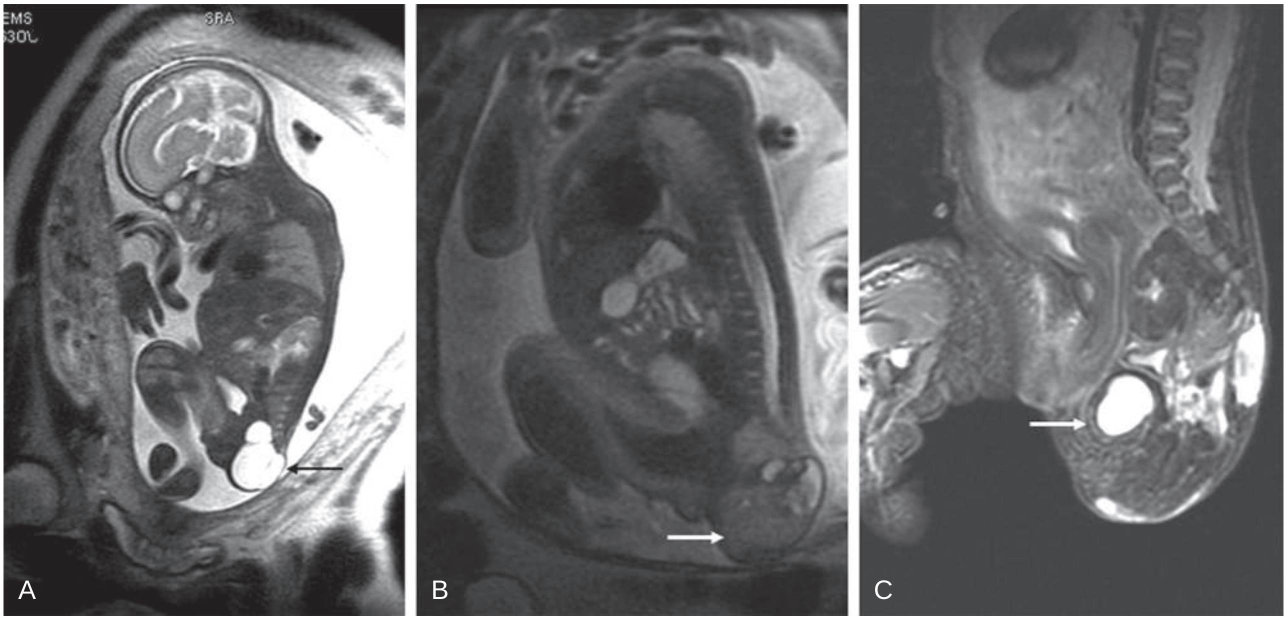

Figure 66-91 Sacrococcygeal germ-cell tumor. **A** and **B**, Prenatal MRI images show both cystic and solid elements within a large presacral mass. **C**, At birth the solid elements predominated, although large cystic spaces were still present.

Approximately 20% of these patients have pulmonary metastases at the time of diagnosis.[279]

These tumors arise from coccygeal tissue elements, and surgical resection must include resection of the coccyx. When complete resection can be accomplished, survival rates are greater than 95% with tumors that have benign mature teratomatous elements. The presence of malignant elements results in much lower rates of long-term survival.[279]

In addition to sacrococcygeal teratomas, other presacral solid masses must also be in the differential, including neuroblastoma and lymphoma. In particular, the distinction between presacral cystic neuroblastoma and a type IV germ-cell tumor may be difficult on the basis of imaging alone (Fig. 66-92). The presence of intraspinal extension, which is more commonly seen in neuroblastomas, is unusual in the setting of sacrococcygeal germ-cell tumors, aiding in the differential diagnosis. Predominantly cystic germ-cell tumors may also be difficult to distinguish from lumbosacral myelomeningoceles or the related fat-containing lipomyelomeningocele. Again the extent of intraspinal involvement, which is best demonstrated by MRI, may help in narrowing the differential diagnosis.

MUSCULOSKELETAL NEOPLASMS

Primary Bone Tumors

Pediatric bone tumors are relatively rare, comprising less than 5% of the new cancer diagnoses in children under the age of 9 years, and between 8% and 11% in children between the ages of 10 and 19 years. Osteosarcoma is the most common primary malignant bone tumor occurring in the first 2 decades of life. The remaining bone malignancies include the Ewing family of tumors (Ewing sarcoma) and primary lymphoma of the bone. Because symptoms are frequently nonspecific, there is often a delay in diagnosis. The goal of the imaging evaluation is to establish a preliminary diagnosis,[330] because about half of the bone lesions detected in children are benign. Based on these preliminary assessments, a more detailed imaging evaluation can then be undertaken. It is beyond the scope of this review to discuss the nonmalignant lesions that may mimic malignancy; however, chronic osteomyelitis, osteoid osteoma, bone cysts, and stress-related injury are all included among the differential considerations for primary bone lesions.[331]

Conventional radiography is essential as a first step in the evaluation.[332] Radiographs afford high spatial resolution, can be readily obtained, are relatively inexpensive, and do not require sedation. Most importantly the radiographs are critical in guiding the next step in the evaluation based on the pattern of bone reaction/involvement and surrounding soft-tissue involvement. MRI is usually the imaging modality of choice to further characterize primary bone lesions.[330,331] MRI sequences should include at a minimum, T1- and T2-weighted imaging in at least two orthogonal planes as well as post–gadolinium-enhanced imaging. Fat suppression sequences are nearly always of value in distinguishing focal areas of enhancement from intramedullary fatty marrow or surrounding soft-tissue fat, whereas non–fat-suppressed T1-weighted sequences are invaluable for delineating the margins of marrow-space involvement. Fluid-sensitive sequences are highly sensitive but lack specificity: tumor, edema, hemorrhage, and focal fluid collections all may show increased signal on fluid-sensitive sequences. More importantly the fluid-sensitive sequences allow the examiner to closely assess the relationship of signal abnormalities in the bone and soft tissues to adjacent neurovascular structures. It remains controversial whether post–gadolinium-enhanced images, simple T1-weighted images, or fat-suppressed

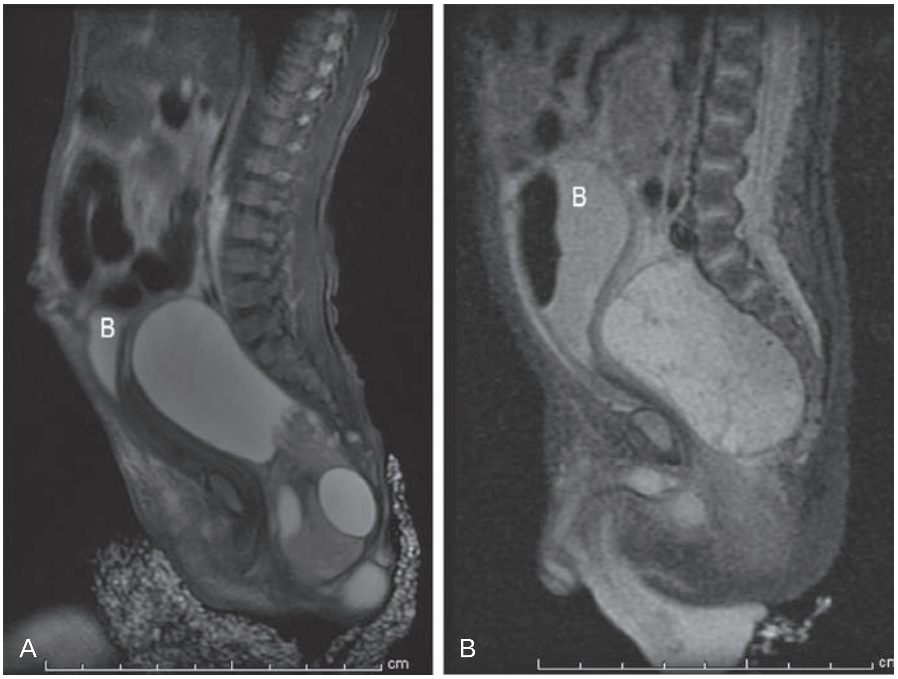

Figure 66-92 Sacrococcygeal germ-cell tumor (**A**) and cystic neuroblastoma (**B**). Two patients with prenatally diagnosed cystic presacral mass. Fluid-sensitive MRI showed similarly appearing complex cystic masses, both compressing the bladder *(B)*, with very similar imaging appearance, emphasizing the importance of including neuroblastoma in the differential for some sacrococcygeal teratomas.

T2-weighted images allow the best discrimination between the true intraosseous tumor margins and surrounding peritumoral edema and bone reaction. Dynamic contrast-enhanced MRI allows tumor vascularity and permeability to be measured directly, and in at one study of osteosarcoma patients, pretreatment patterns of intratumoral blood flow were identified as prognostic factors for event-free and overall survival, as well as being indicative of a histologic response to neoadjuvant therapy.[333] The technical challenges of performing these studies combined with complex postprocessing requirements has limited the more widespread acceptance of this technique.

CT has a relatively limited role in assessing the primary bone lesions, given the increased use of MRI. However, for focal bone lesions such as osteoid osteoma, CT is very helpful in characterizing the focal osseous abnormality. In addition, for primary bone tumors, particularly Ewing sarcoma involving the chest wall and ribs, CT may be preferable. The staging evaluation of primary bone tumors must also include a CT of the chest to assess for pulmonary metastatic disease. The use of bone scintigraphy, either using ^{99m}Tc or ^{18}F, is considered standard of care for assessing multifocal sites of disease.[90] FDG-PET imaging, although not in routine clinical practice, has been shown in several studies to be effective in detecting sites of lymph node spread and metastatic disease outside of the primary site and in helping determine the margin of metabolically active tumor involvement.[176,183,334-336] In addition FDG-PET has been effective at showing early responses to chemotherapy, and studies have shown that early responses to chemotherapy, manifest as decreased metabolic activity and decreased FDG uptake, correlate with improved outcome and overall survival.[174,183,337-339]

Osteosarcomas

Osteosarcomas are the most common primary bone tumor occurring in children older than the age of 10 years (Ewing sarcoma being more common in younger children).[340-342] This may relate to the period of rapid bone growth occurring in early to mid adolescence, which corresponds to the peak incidence of osteosarcoma. The majority of osteosarcomas are of the classic high-grade histologic type with telangiectatic and surface osteosarcomas occurring less often (the latter two entities being divided into parosteal and periosteal subtypes). Osteosarcomas most commonly occur in the metaphysis of the rapidly growing ends of the long bones including the distal femur, proximal tibia, proximal femur, and proximal humerus. Involvement of the axial skeleton and flat bones is much less common, except where osteosarcoma has developed secondary to radiation treatment or chemotherapy. At diagnosis, approximately 20% of patients have pulmonary metastatic disease detectable by chest CT. Other sites of metastatic disease spread are unusual.

The radiographic appearance of osteosarcoma varies widely; however, the typical lesion is an aggressive, destructive lesion centered in the metaphysis (Fig. 66-93). Smaller lesions may show periosteal reaction, most commonly a sunburst-type reaction. The Codman triangle formation indicates periosteal new-bone formation with the free edge of the periosteal new bone disrupted by growth of the tumor mass (Fig. 66-94). A lamellated or onion skin–type periosteal reaction may also be seen in

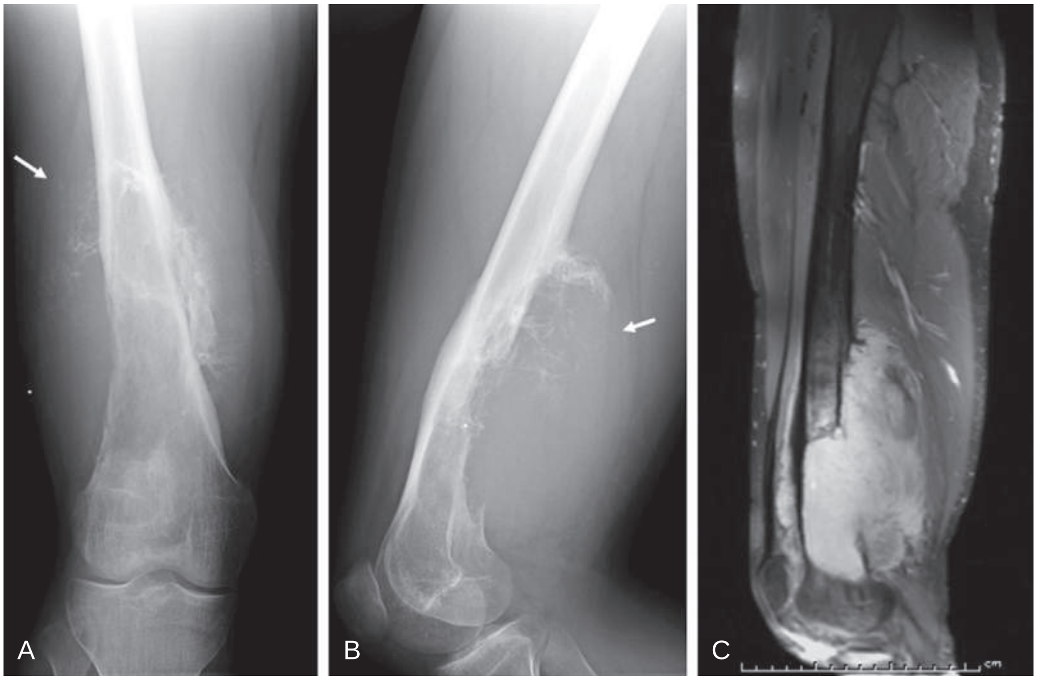

Figure 66-93 Osteosarcoma in a 19-year-old male with an enlarging right-leg mass. **A** and **B**, Radiographs show a large destructive lesion with extensive periosteal reaction. A large soft-tissue mass is also evident on the radiographs *(arrows)*. **C**, MRI shows better delineation of the associated soft-tissue mass and the extent of osseous involvement.

smaller lesions; however, this is more typically associated with Ewing sarcoma. Although the diagnosis of osteosarcomas is usually suggested by plain films, the films are relatively insensitive at determining the extent of disease. As noted, MRI is essential in determining the extent of long-bone involvement, the degree of soft-tissue involvement, and the extent of invasion into adjacent neurovascular structures (see Fig. 66-94 and Fig. 66-95).[341,343] Although epiphyseal involvement and crossing of the growth plate by osteosarcoma is seen as unusual, reports have suggested that this may occur in as many as 80% of patients.

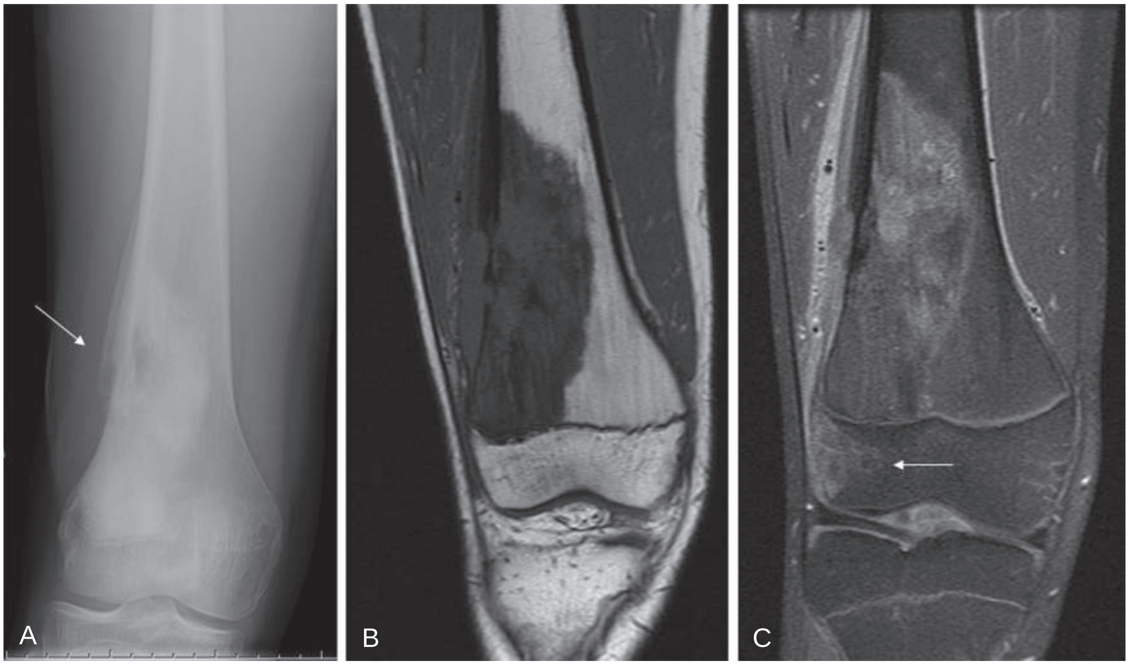

Figure 66-94 Osteosarcoma in a 16-year-old patient with leg swelling. **A**, Radiograph of the right femur shows a sclerotic lesion in the distal femoral metaphysis, with periosteal elevation and Codman's triangle *(arrow)*. **B** and **C**, T1-weighted MRI and post-Gd T1-weighted imaging show the extent of bone involvement and raise concern for epiphyseal extension of the tumor *(arrow)*.

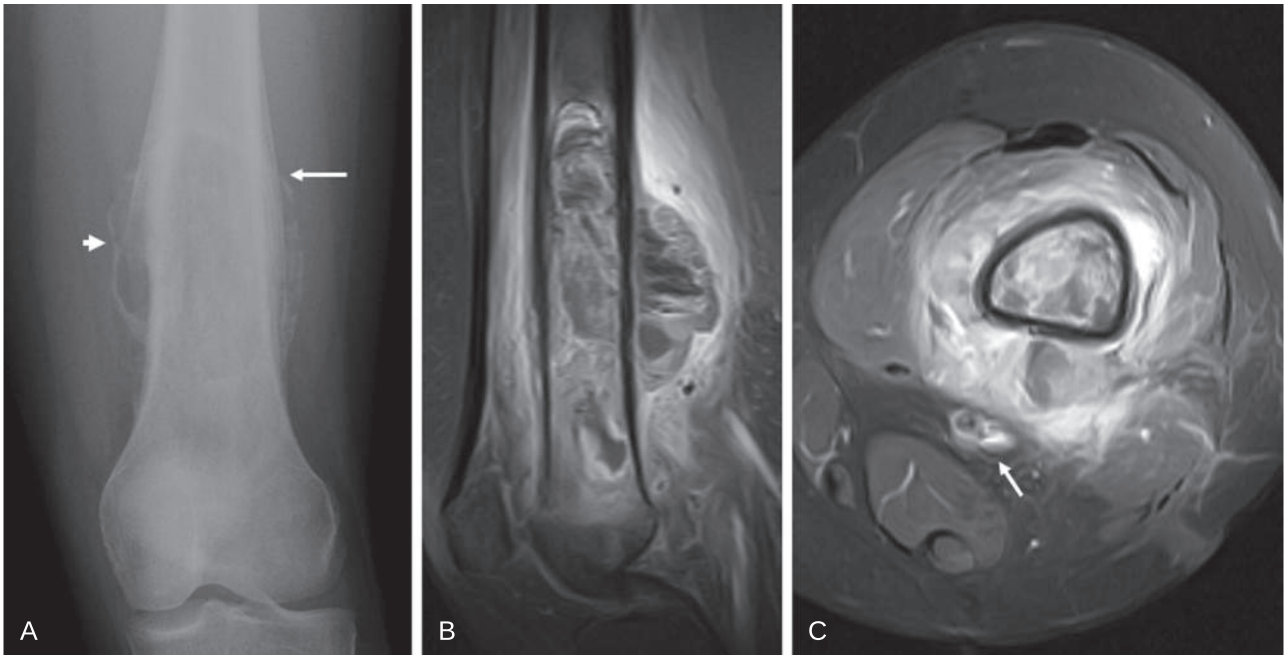

Figure 66-95 14-year-old girl with osteosarcoma. **A**, The radiograph shows a large, distal femoral destructive lesion with osteoblastic activity, lamellated periosteal reaction *(arrow)*, and a Codman triangle *(arrowhead)*. **B**, Contrast-enhanced MRI shows the associated soft-tissue mass to better advantage, as well as the extent of bone involvement. **C**, The axial MRI image shows the mass abutting the neurovascular bundle *(arrow)* but not encompassing it.

MRI is also helpful in characterizing the primary lesion. The presence of fluid-fluid levels, common to telangiectatic osteosarcoma, are best demonstrated by MRI (Fig. 66-96). The initial imaging evaluation should also assess for the presence of pathologic fracture and must include the joint proximal and distal to the primary lesion to aid in surgical planning and decision making. Skeletal scintigraphy and chest CT are necessary for the staging evaluation to assess for locoregional and distant metastatic disease.[341] Follow-up imaging is usually dictated by individual treatment protocols but typically includes imaging of the primary site of disease and chest

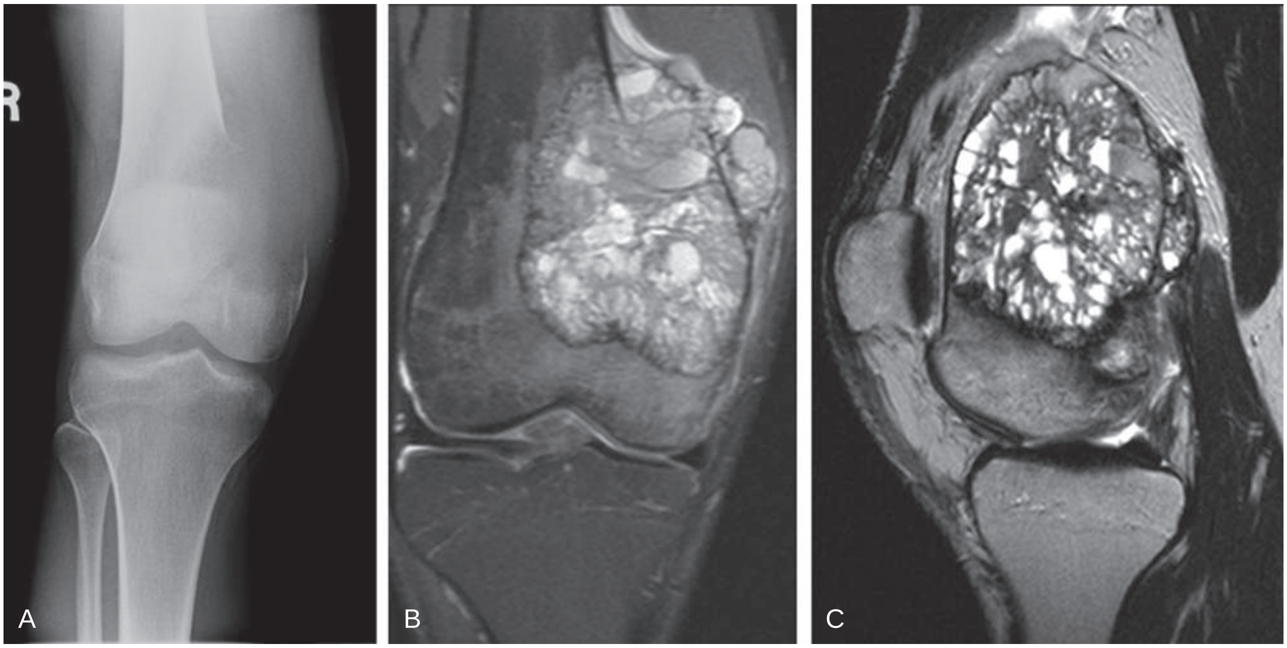

Figure 66-96 Osteosarcoma. This 18-year-old male experienced leg pain and swelling. **A**, Radiographs show a destructive lesion in the distal femur with an associated soft-tissue mass. Gadolinium contrast-enhanced (**B**) and fluid-sensitive FSEIR (**C**) MRI images demonstrate multiple fluids/fluid levels with heterogeneous contrast enhancement. The appearance is common in telangiectatic osteosarcoma, but in this patient with high-grade metastatic osteosarcoma the imaging features were the result of multiple solid and necrotic elements within the tumor.

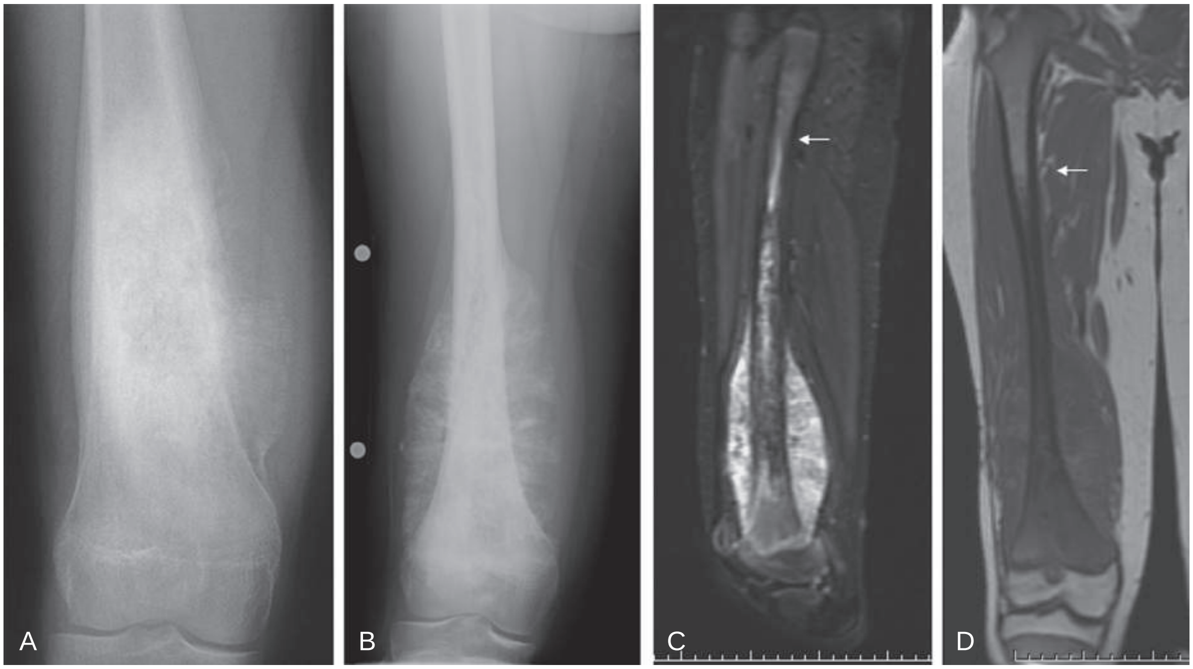

Figure 66-97 Ewing sarcoma. Radiographs from two patients with Ewing sarcoma show the "onion-skin" periosteal reaction characteristic of this tumor (**A**) and the sunburst periosteal reaction that is also commonly seen (**B**). FSEIR and T1-weighted MRI images from the patient demonstrate intramedullary high signal on the FSEIR images (**C**) and corresponding loss of normal intramedullary fat signal (**D**), indicating more widespread extension of tumor than was suggested by the radiographic findings and highlighting the importance of MRI in evaluating extent of disease in these patients.

CT. The presence of pulmonary nodules, both at diagnosis and as a site of relapse, is important prognostically,[344] and chest CT remains an essential part of the posttherapy evaluation in these patients. Unfortunately, there are no specific imaging features to distinguish benign from malignant pulmonary nodules,[22,186] and surgical resection remains essential for both definitive diagnosis and potential cure.[23]

Ewing Sarcomas

Ewing sarcomas are most often poorly differentiated tumors arising from the bone, although they may also arise from adjacent soft tissues. The primative neuroectodermal derivative of this tumor is known as the peripheral PNET (PPNET). Ewing sarcomas arising in a chest wall make up about 10% of the Ewing family of tumors. Clinically, pain and a palpable mass are the most common presenting complaints. As with osteosarcoma, the imaging evaluation should be initially directed at characterizing the primary site of abnormality. Anatomically, Ewing sarcomas occur with roughly equal distribution in the axial and appendicular skeleton, with about two thirds occurring in the pelvis and/or lower extremities. At the time of presentation, the size of the mass and extensive local invasion may make it difficult to determine whether the lesion has arisen primarily within the bone or within the surrounding soft tissue. Metastatic disease is also common at the time of diagnosis, with sites of metastatic disease reflecting hematogenous spread, including lung, bone, and bone marrow.

Radiographically, Ewing sarcoma of the bone is primarily a lytic lesion with a permeative destructive appearance.[345] The onion-skin or lamellated periosteal reaction is characteristically described with Ewing sarcoma, although it is not specific for this diagnosis. Other forms of periosteal reaction are also seen (Fig. 66-97), reflecting the variable degree of bone destruction and bone response to the tumor. There is usually a large accompanying soft-tissue mass. Particularly in the axial skeleton (pelvis and ribs), the soft-tissue component may predominate.

Plain radiographs should include imaging of the involved long bones, chest, and/or pelvis. MRI is indicated for further evaluating the appendicular skeleton and long bones, and as with osteosarcoma the entire length of the bone including the proximal and distal joints should be included. The choice of MRI pulse sequence is similar to that for osteosarcoma but should include at a minimum T1- and fat-suppressed T2-weighted images in orthogonal planes as well as post–gadolinium-enhanced images. The axial images, particularly T2-weighted, are useful for demonstrating the extent of subperiosteal and periosteal extension. Either sagittal or coronal images are effective at defining the margin of bone-marrow involvement and surrounding tissue edema.

Rib and chest wall lesions are best evaluated by CT. With multiplanar 3D image reconstruction capabilities on modern CT scanners, the extent of osseous involvement and adjacent lung/pleural involvement can usually be adequately demonstrated by CT (Fig. 66-98). For paraspinal lesions, MRI may be necessary to delineate intraspinal invasion. MRI is also useful in characterizing subtle abnormalities such as chest-wall muscle involvement and neurovascular involvement, particularly in the upper thorax and lung apices.

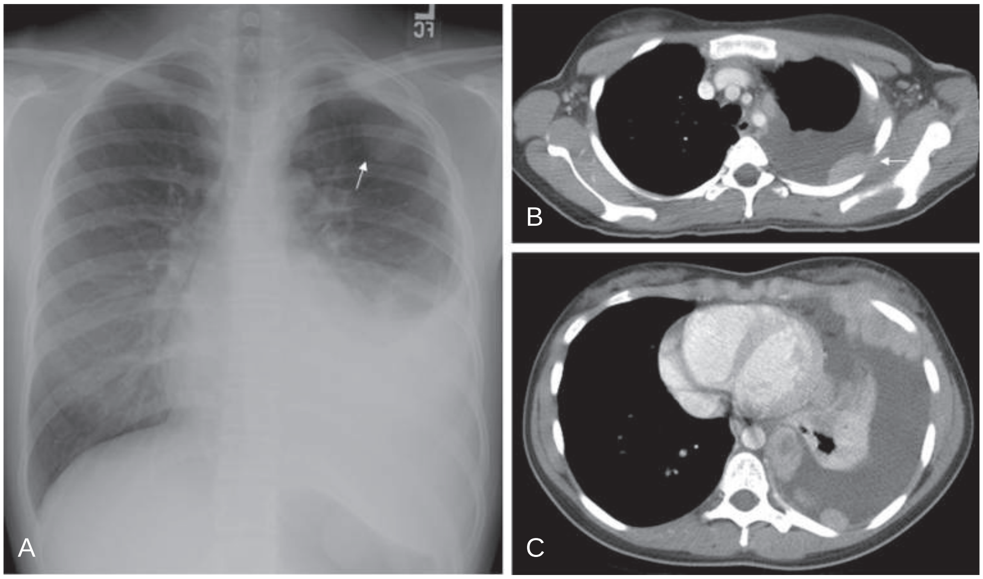

Figure 66-98 Ewing sarcoma of the chest wall. A 14-year-old girl with chest pain had a chest x-ray (**A**) that shows a large, left pleural effusion and multiple nodular densities *(arrow)* apparently arising from the chest wall/pleura. Contrast-enhanced CT (**B** and **C**) show extensive soft-tissue masses lining the chest cavity with large effusion and left lower lobe collapse. Biopsy showed Ewing sarcoma.

In contrast to osteogenic sarcoma, Ewing sarcoma does not typically show the presence of soft-tissue calcifications. Whole-body bone scintigraphy is effective at delineating sites of skeletal involvement; however, there is no clear evidence that skeletal scintigraphy is superior to MRI in characterizing local disease. FDG-PET imaging has been advocated in the staging evaluation of Ewing sarcoma, particularly with respect to identifying sites of occult bone-marrow metastatic disease. In addition, as with osteosarcoma, the use of FDG-PET has been advocated both for staging[336] and for monitoring response to therapy (Fig. 66-99).[80,174,335,337,339]

Other Bone Tumors

Primary lymphoma of the bone is a relatively unusual site of presentation in non-Hodgkin lymphoma but must be included in the differential diagnosis of a primary destructive lesion with intramedullary involvement. Radiographically the evaluation is similar to Ewing sarcoma, and biopsy is usually needed to confirm the diagnosis.

Although they are not primary bone neoplasms, leukemia and Langerhans-cell histiocytosis are both pediatric neoplastic conditions that may manifest with bone involvement (see Fig. 66-3). Leukemia, described below, often produces metaphyseal lucency and may result in an aggressive, permeative, moth-eaten appearance to the bone, occasionally accompanied by periosteal reaction. Pain is also common at this stage of bone reaction to the leukemic infiltration. Langerhans-cell histiocytosis can manifest either as localized disease or widespread osseous involvement. Typical osseous lesions are lytic on conventional radiographs. Because they are relatively slow growing and do not elicit a significant response from the surrounding bone, these lesions may go undetected by bone scintigraphy, and skeletal survey is still advocated to assess for the extent of osseous involvement in Langerhans-cell histiocytosis. Recent studies have also suggested that FDG-PET may be more sensitive both in determining sites of intraosseous involvement and in determining sites of soft-tissue involvement that would otherwise go undetected either by conventional scintigraphy or skeletal survey.[3]

Muscle/Soft-Tissue Tumors

The nonosseous musculoskeletal malignancies of childhood are typically sarcomas that arise from immature mesenchymal tissue. Rhabdomyosarcomas of skeletal-muscle origin comprise about half of the pediatric soft-tissue sarcomas.[342,346] The nonrhabdomyomatous soft-tissue sarcomas include fibrosarcomas, synovial sarcomas, alveolar soft-part sarcomas, malignant fibrous histiocytomas, and PPNETs. Ultimately the distinction between these different histiologic subtypes is made pathologically. The imaging approach is directed at determining the size and extent of primary tumor involvement, the relationship to critical adjacent structures such as nerves and blood vessels, and local involvement of bone or regional lymph nodes. All of the soft-tissue sarcomas have a propensity to metastasize to the lung, and a CT of the chest should be performed at the time of diagnosis. Bone scintigraphy is also indicated to assess for additional sites of skeletal involvement, and FDG-PET is increasingly be used for staging and response assessment in pediatric soft-tissue sarcoma.

Rhabdomyosarcomas are the most common soft-tissue sarcomas of childhood, making up more than half of all soft-tissue sarcomas in children.[342] Although the head and neck and genitourinary tract are common sites of rhabdomyosarcoma presentation, about one fourth of these tumors are also located in the extremities. These are typically of the alveolar or undifferentiated histologic type.[347] The imaging characteristics are not specific, but feature a

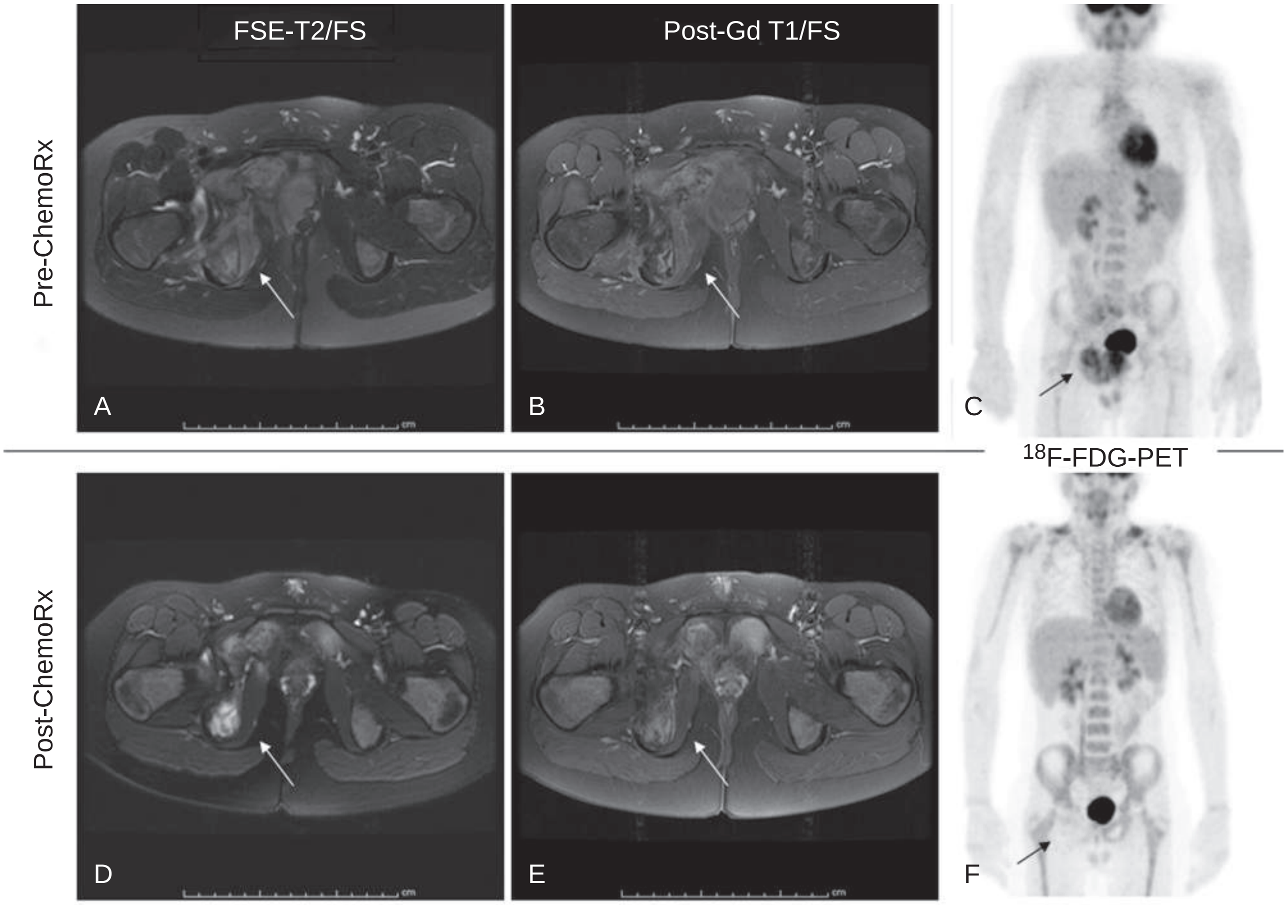

Figure 66-99 Ewing sarcoma response assessment. Images are of a 10-year-old child with nonmetastatic Ewing sarcoma of the right pelvis. T2-weighted (**A**) and contrast-enhanced T1-weighted (**B**) MRI images show an ill-defined enhancing mass centered in the right ischium with soft extension into the surrounding pelvis *(arrows)*. Pretreatment FDG-PET imaging (**C**) shows moderately intense uptake in the mass. After chemotherapy, MRI (**D** and **E**) shows persistent areas of increased T2 signal and enhancement *(arrows);* FDG-PET shows no residual metabolic activity in the mass (**F**), demonstrating an excellent response to therapy and suggesting that the MRI findings may relate to a necrotic tumor and enhancing scar/granulation tissue rather than active disease.

T2-bright lesion localized in the deep soft tissues with extension along fascial planes (Fig. 66-100). After contrast infusion, these tend to be hypervascular tumors with bright enhancement. FDG-PET has been shown in several studies to yield intense FDG uptake and is likely to be of value in identifying sites of occult disease at the time of staging and in assessing response to therapy.[183,184,281]

Synovial Sarcoma

Synovial sarcomas typically occur in patients during their teenage years. Synovial sarcomas are the most common nonrhabdomyosarcomatous soft tissues in children,[346] and despite their name, they arise from undifferentiated mesenchymal cells that are typically located in a paraarticular location. They are more common in the lower extremities than in the upper extremities or axial skeleton and are often mistaken for other benign or incidental conditions.[348] Conventional radiographs are indicated for extremity lesions and show calcifications in about 30% of cases. MRI shows a lobulated lesion that is usually isointense to muscle on T1-weighted images and isointense to slightly hyperintense on T2-weighted images with a relatively homogeneous appearance.[349] After contrast infusion, there is typically intense enhancement (Fig. 66-101). Although these findings are not specific for synovial sarcoma, the presence of a lobulated calcified lesion with the described MRI signal characteristics should suggest the diagnosis.

The clinical presentation is typically of a painless mass. Median duration of symptoms before presentation is approximately 14 months. The staging evaluation is important in predicting the overall survival of these patients. Patients with localized disease and/or with disease allowing gross total resection have an estimated 80% 5-year overall survival, as compared with patients who have metastatic disease at diagnosis and for whom the diagnosis is nearly always fatal.[350] Because these lesions most often occur in extremities, they may mimic benign disease such as synovial or ganglion cysts. The MRI examination must therefore include contrast enhancement in order to discriminate between a solid enhancing lesion and a predominantly fluid-containing cystic lesion (Fig. 66-102). Because of the importance of local control, imaging is also essential in determining resectability and in establishing the preoperative margins for surgical planning.

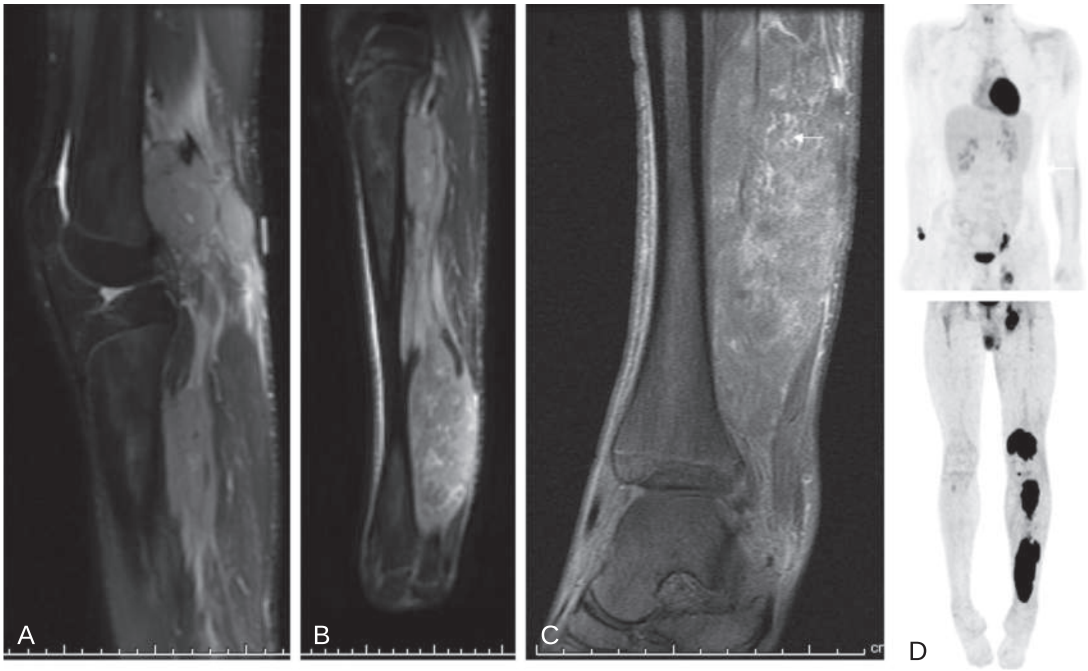

Figure 66-100 Rhabdomyosarcoma in a 16-year-old patient with a left leg mass. **A** and **B**, MRI findings show a T2 bright, enhancing (**C**) lesion localized in the deep soft tissues of the calf with extension proximally along fascial planes into the popliteal fossa. FDG-PET shows multiple sites of disease, including left inguinal lymph-node involvement that would not have been detected on the MRI. Biopsy showed alveolar rhabdomyosarcoma.

Tumor size has also been shown to be a key prognostic factor in synovial sarcoma, with lesions less than 5 cm resulting in a metastasis-free survival rate greater than 75%, in contrast to lesions greater than 5 cm in size. In patients with these lesions, the metastasis-free survival rate falls to less than 50%.[350] Synovial-cell sarcomas are typically FDG-avid tumors, and FDG-PET imaging should be considered at the time of staging to assess for locoregional lymph node spread and distant sites of metastatic disease that would adversely affect prognosis (see Fig. 66-102).

Malignant Peripheral Nerve-Sheath Tumor and Neurofibromatosis Type 1

Individuals with NF1 are at risk of developing benign and malignant tumors; the leading cause of mortality among these individuals is the development of malignant peripheral nerve-sheath tumors (MPNSTs). MPNSTs result from malignant degeneration of benign NF1 lesions, including plexiform neurofibromas (PNs).[351] In patients with extensive plexiform lesions, the diagnosis of malignant degeneration is challenging and classically relies on changes in lesion size and/or localized or unremitting pain, although these features are neither sensitive nor specific. Other than increase in size, no discriminating MRI features have been described to identify PNs potentially undergoing malignant degeneration into MPNSTs. A number of studies using FDG-PET in NF1 have demonstrated a significant difference in mean standardized uptake values (SUV) between benign and malignant lesions.[352-354] In a retrospective study of 19 children with NF1 who had cross-sectional imaging and correlative histopathologic data, Tsai et al. provided further data supporting the hypothesis that benign and malignant lesions are distinguishable by FDG-PET imaging in children and that there is a correlation between SUV_{max} and tumor grade.[355] It is the authors' current practice to perform FDG-PET imaging on all patients who have NF1 with new clinical symptoms, change in lesion size, or identification of new lesions by CT or MRI. Lesions with an SUV_{max} greater than 4 are considered worrisome, warranting either more intensive monitoring or surgical resection (Fig. 66-103).

Infantile (Desmoid-Type) Fibromatosis

Infantile fibromatosis is a benign fibrous proliferation, although it can be locally aggressive and deforming.[356] Infantile desmoid-type fibromatosis must be distinguished from the congenital generalized fibromatosis, also known as *infantile myofibromatosis*.[357] This latter disorder is characterized by lesions consisting of both smooth muscle and fibroblastic spindle cells in contrast to the more differentiated fibroblastic cells seen in desmoid fibromatosis. The presence of deep soft-tissue involvement as well as visceral involvement of organs such as lung and liver has a worse prognosis than localized disease. The extent of involvement is optimally determined by MRI (Fig. 66-104), with lesions typically characterized by low signal on both T1- and T2-weighted sequences because of the relatively high collagen content in these tumors.[357]

It may be difficult based on imaging findings alone to distinguish between aggressive multifocal fibromatosis and congenital fibrosarcoma. The desmoid-type lesions, in contrast, tend to be localized and have a less aggressive appearance.

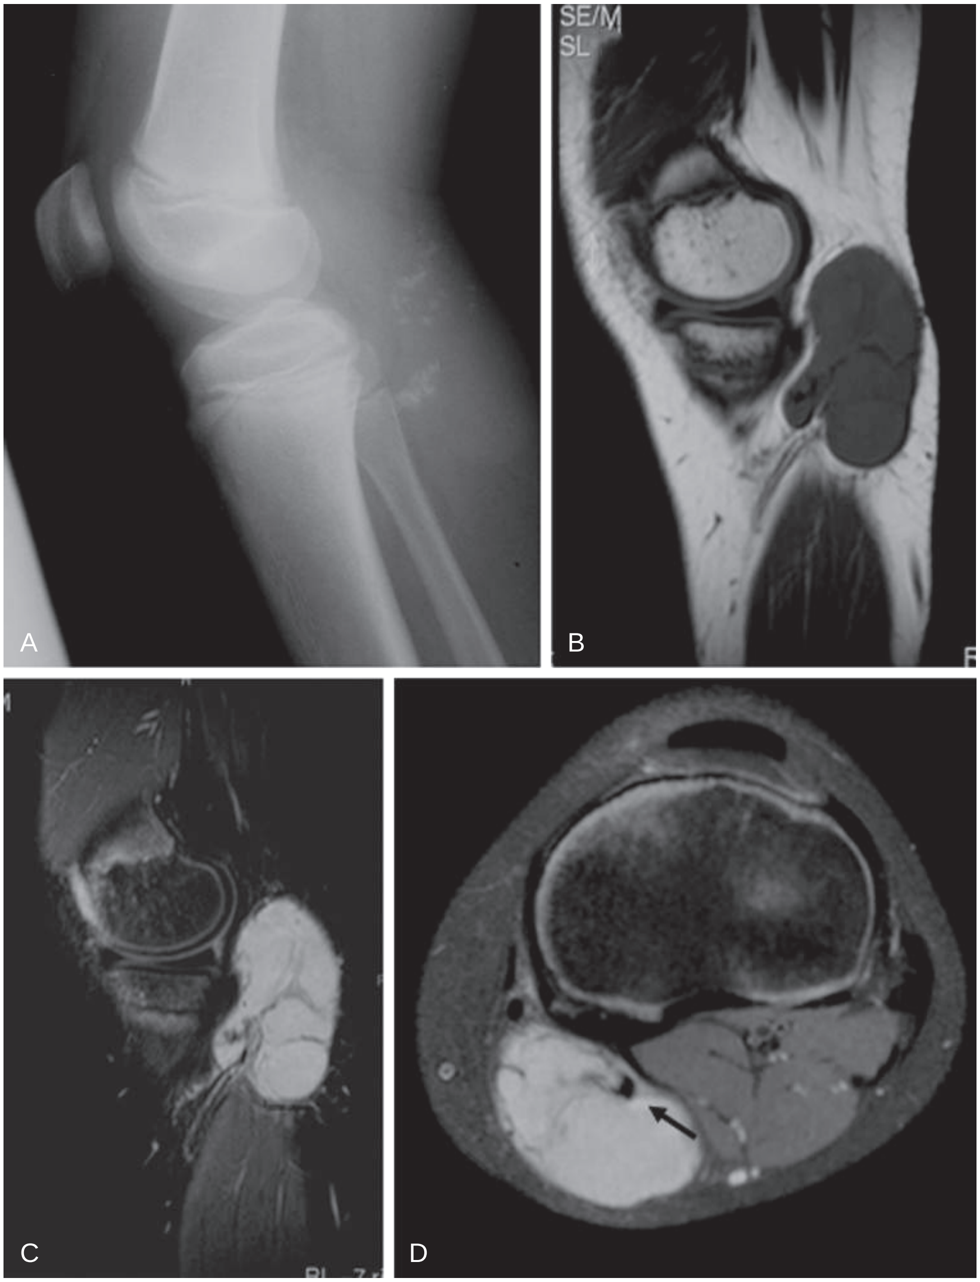

Figure 66-101 Synovial sarcoma. **A**, Radiograph of an 11-year-old child with a palpable leg mass showed a calcified mass behind the knee. MRI shows lobular mass in the medial compartment posterior to the knee, encasing the semi membranous tendon *(arrow)*, characterized by low signal on T1-weighted images (**B**), high signal on T2-weighted images (**C**) and intense contrast enhancement (**D**). These features are all characteristic findings in synovial sarcoma.

Other mesenchymal tumors, such as alveolar soft-part sarcomas, epithelioid sarcomas, and malignancy fibrous histiosarcomas are very rare in children and do not have distinctive imaging characteristics. As with the other mesenchymal tumors, lesions are typically isointense to slightly hyperintense on both T1- and T2-weighted images, with variable patterns of enhancement.

The distinction between liposarcoma and the benign lipoblastoma cannot be made on the basis of imaging alone, with both lesions showing high signal-intensity on T1-weighted images, decreased signal intensity on T2-weighted images, and minimal enhancement. As with the other malignant sarcomas, metastatic disease to the chest must be excluded, and the staging evaluation should include chest CT.

LYMPHOPROLIFERATIVE NEOPLASMS

Leukemias

Of the pediatric cancers approximately one third are leukemias, and together with brain tumors, leukemia accounts for over half of the childhood tumors.

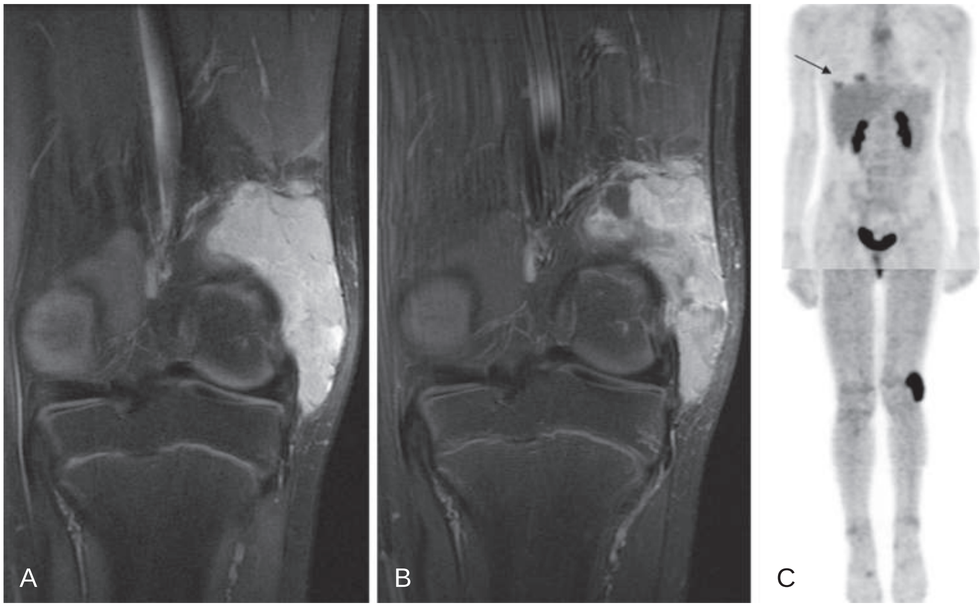

Figure 66-102 Synovial-cell sarcoma. Coronal fat-suppressed PD (**A**) and post-Gd T1-weighted MRI (**B**) shows a lobulated high signal-intensity enhancing lesion. The location and bright signal on fluid-sensitive sequences could be mistaken for a benign process; the pattern of contrast enhancement confirms a worrisome lesion. FDG-PET (**C**) shows intense uptake at the primary site and at least two focal pulmonary metastatic lesions *(arrow)*. This pattern of involvement and spread is common for synovial-cell sarcoma.

More than 75% of pediatric leukemia is acute lymphoblastic leukemia (ALL),[358] and the majority of the patients have B-lymphoblastic ALL, with 15% to 20% having T-cell ALL and 1% to 2% with mature B-cell ALL. Acute myelogenous leukemia (AML) makes up 15% to 20% of pediatric leukemia; the remainder are leukemic subtypes that are uncommon in children, such as chronic myelogenous leukemia and juvenile myelomonocytic leukemia.

The most common presenting symptoms and physical examination findings are nonspecific and include fever, bleeding, bone pain, lymphadenopathy, and splenomegaly. In addition to the fatigue, pallor, and anorexia, which

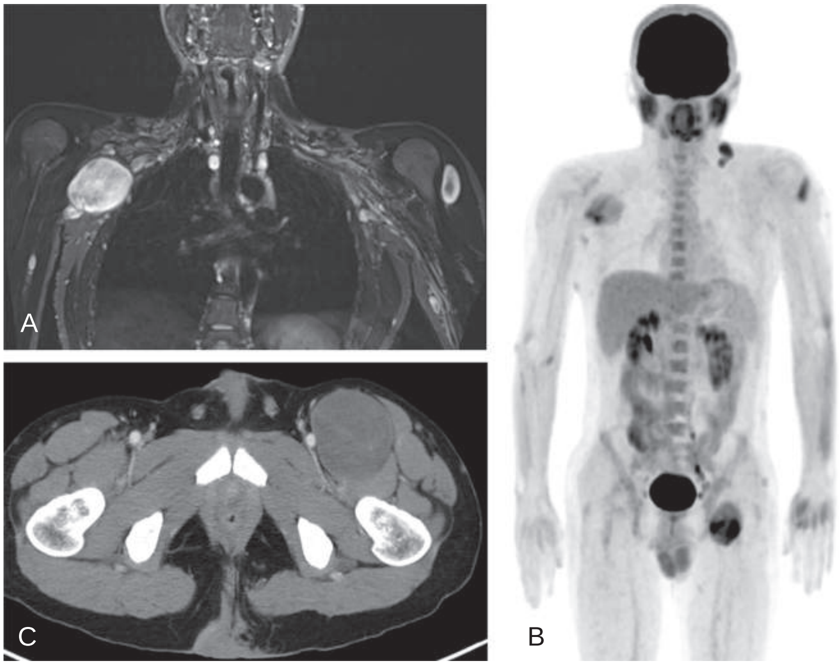

Figure 66-103 23-year-old patient with NF1 and multiple painful lesions. MRI shows T2-bright lesions in the right axilla and left deltoid (**A**), with corresponding FDG uptake (**B**). A CT scan of the pelvis shows low density left inguinal lesion (**C**) that has corresponding intense FDG uptake (**B**). SUV values and correlative histopathology of these lesions were: Left neck (not shown on MR) SUV: 4.97, atypical neurofibroma; right axilla SUV: 4.94, atypical neurofibroma; left deltoid SUV: 4.15:,atypical neurofibroma; left inguinal SUV: 9.33, low-grade malignant peripheral nerve sheath tumor.

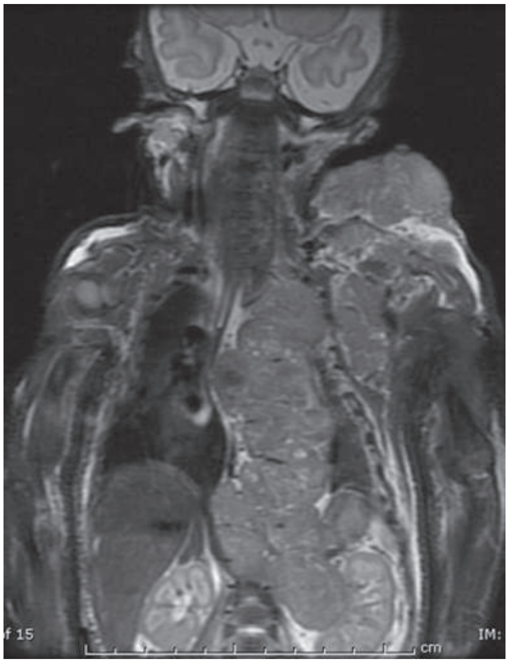

Figure 66-104 Infantile fibromatosis in a 4-week-old infant. The MRI shows extensive mediastinal, retroperitoneal, and intraabdominal disease. Biopsy showed infantile fibromatosis.

are seen in almost all patients with leukemia, hepatosplenomegaly and fever are seen in approximately two thirds of cases.[127]

Because of the nonspecific nature of presenting symptoms and physical examination findings, radiologic imaging may be useful in directing the next step in the evaluation. Common imaging findings include pulmonary edema secondary to high output cardiac failure in the setting of peripheral leukemic blast crisis (related to anemia); organomegaly including enlargement of the spleen, liver and heart; and pulmonary airspace opacities (related to leukostasis or infection).[359] Skeletal changes can range from subtle metaphyseal lucent bands to frank bone destruction resulting from leukemic infiltration. CNS hemorrhage may be encountered as a result of leukostasis and thrombocytopenia in patients with high peripheral leukemic-cell counts.[360] Although such imaging finding alone do not make the diagnosis of leukemia, the initial imaging evaluation can be critical in assessing the overall physiologic burden of the patient's disease.

Imaging Findings

Peripheral skeletal lesions may be detected on conventional radiographs in approximately 25% of patients newly diagnosed with ALL.[127] In the patient with fatigue and poorly localized bone pain, metaphyseal lucent bands (leukemic lines) may be seen (Fig. 66-105). This finding was initially thought to represent leukemic infiltration in the submetaphyseal bone, although the discovery of elevated parathyroid hormone levels in patients with leukemia suggests paraneoplastic effects on bone resorption likely contribute to the observed radiographic changes.[361] Metaphyseal lucent lines are not unique to leukemia and may also be seen in other marrow-infiltrative malignancies such as neuroblastoma (see Fig. 66-3) and lymphoma and in response to physiologic stress such as infection, systemic inflammatory reactions, and radiation.

Metaphyseal lucent lines may be difficult to distinguish from the diffuse metaphyseal lucency, which represents a combination of direct leukemic infiltration of the bone and accompanying bone resorption. This pattern of infiltration typically results in a broad irregularity and more poorly demarcated pattern of metaphyseal lucency. It is also associated with pain and localized tenderness, and depending on the degree of bone destruction it may also be accompanied by focal lytic lesions. Leukemic infiltration of the bone can also yield a moth-eaten appearance with a marked pattern of periosteal reaction.

More advanced imaging techniques such as MRI may be helpful in demonstrating the extent of leukemic infiltration by showing both focal and diffuse replacement of

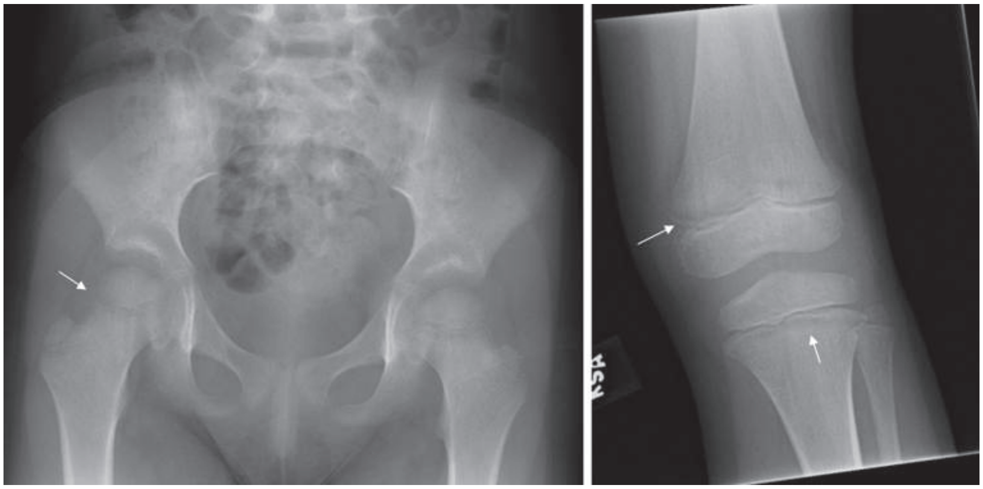

Figure 66-105 Leukemic lines. A 4½-year-old had child with limp and leg pain. Radiographs of the hips, pelvis, and knees show submetaphyseal lucency *(arrow)* and loss of the normal trabecular architecture, particularly in the femoral necks. Bone marrow aspiration confirmed leukemia.

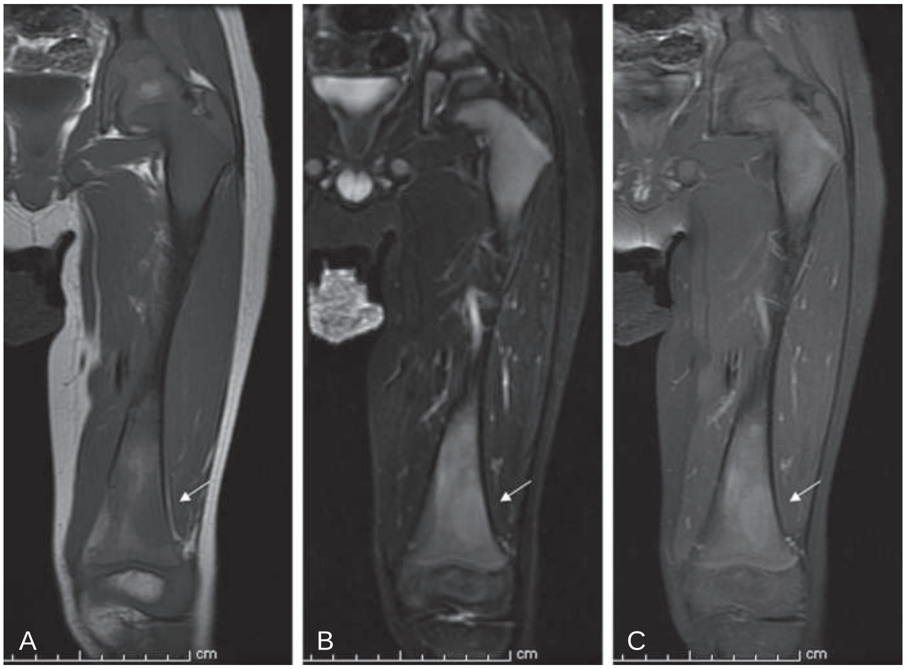

Figure 66-106 MRI of marrow infiltration in leukemia. A 3-year-old child experienced persistent limp and lower extremity pain. MRI showed patchy areas *(arrows)* of marrow replacement (A), heterogeneous increased signal (**B**), and enhancement (**C**) suggestive of diffuse marrow infiltration. Bone marrow aspiration confirmed B-cell ALL.

normal fatty marrow signal (Fig. 66-106).[127,362] However, heterogeneous patterns of marrow signal are a normal finding in children as hematopoietic marrow gradually converts to fatty marrow. Furthermore, therapeutic agents that stimulate bone-marrow recovery after ablative chemotherapy (e.g., granulocyte colony stimulating factor [G-CSF]) can mimic leukemic marrow replacement, and the extent of leukemic infiltration may be difficult to determine on the basis of MRI.[363,364]

In the setting of T-cell ALL, children and adolescents commonly experience wheezing as a result of accompanying large mediastinal masses (Fig. 66-107). The diffuse thymic infiltration seen in T-cell ALL (and T-cell lymphoblastic lymphoma) results in a bland, homogeneous-appearing mediastinal mass (Fig. 66-108). Pericardial and pleural effusions are common, as is leukemic infiltration of the kidneys. Despite the bulky disease that is often encountered at the time of presentation, T-ALL and lymphoblastic lymphomas respond rapidly to chemotherapy (see Fig. 66-33), and within a short time, radiographic studies typically return to normal, although the significance of incomplete response of the mediastinal mass to therapy with respect to overall outcome is uncertain.[365]

Childhood Acute Myelogenous Leukemia

AML represents a heterogeneous group of leukemias encompassing both the spectrum and extent of myeloid differentiation.[366] When patients with AML have high peripheral blast counts (leukocyte counts greater than 100,000/mm^3), clinical leukostasis may result and is characterized by global CNS changes or respiratory distress caused by pulmonary vascular involvement. Imaging findings in the brain may suggest diffuse microvascular thrombi (Fig. 66-109) without focal neurologic signs. CNS changes secondary to leukostasis may be difficult to detect by CT and standard MRI sequences, but they are readily demonstrated on paramagnetic susceptibility-sensitive gradient echo sequences because of the paramagnetic effects of hemoglobin breakdown products (i.e., hemosiderin) accumulating at sites of microvascular thrombus formation.

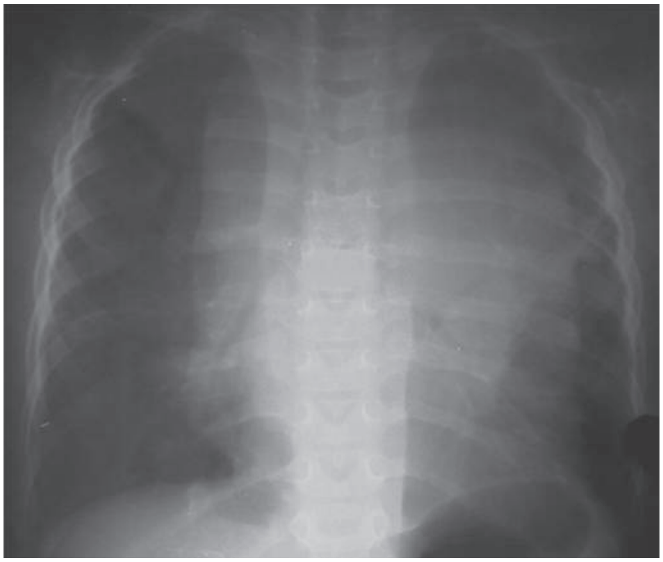

Figure 66-107 T-cell ALL in a 4-year-old child with first-time wheezing. Chest x-ray shows large mediastinal mass and narrowing of the proximal bronchi and air bronchograms, suggesting airway compression.

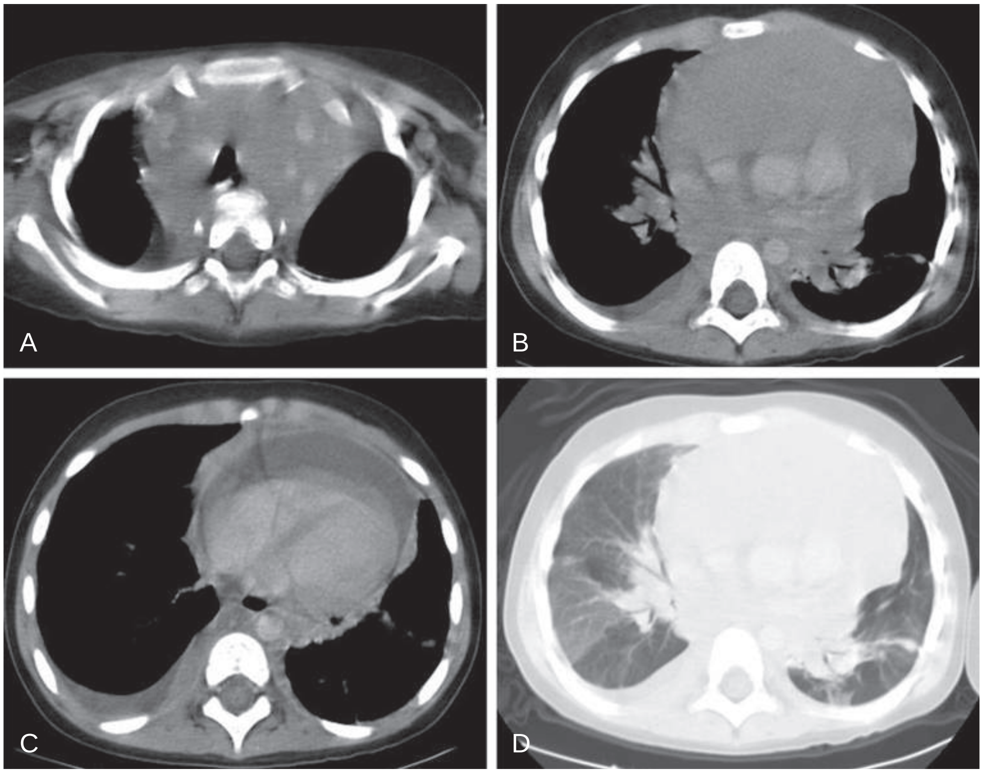

Figure 66-108 T-cell ALL. Shown are images of a 4-year-old child (see Fig. 66-107) with wheezing and mediastinal mass. Contrast-enhanced chest CT shows findings typical of T-cell lymphoblastic lymphoma, including mediastinal mass extending into the neck (**A**) with homogeneous density infiltrating the thymus (**A** and **B**). The mass causes marked airway compression and bronchial narrowing (**A** and **B**) and is associated with pericardial and pleural effusions (**C**) and mosaic lung attenuation (**D**) indicative of air-trapping and airway obstruction. Based on bone marrow involvement of greater than 50% marrow, the patient was diagnosed with T-cell lymphoblastic leukemia with a mediastinal mass.

Acute promyelocytic leukemia (APML) accounts for 5% to 10% of childhood AML and characteristically presents with a severe consumptive coagulopathy that is further exacerbated by cytotoxic chemotherapy because of cell lysis and release of procoagulant intracellular contents. The resulting coagulopathy can result in clinically significant bleeding, necessitating emergent imaging studies to assess for cerebral hemorrhage, which can be profound and rapidly progressive (see Fig. 66-109).

Extramedullary forms of AML, also called *chloromas* and *granulocytic sarcomas,* are seen in up to 10% of patients with AML and are also encountered in chronic myelocytic leukemia (CML) and myelodysplasia.[367] They are commonly asymptomatic; however, CNS involvement can result in mental status changes and lead to focal neurologic deficits. CNS chloromas are usually extraaxial and contiguous with the meninges. They may be virtually undetectable by CT, where they have similar to slightly increased attenuation relative to normal cortex. On MRI, these lesions are typically hypointense to isointense on T1-weighted imaging and heterogeneously isointense to hyperintense on T2-weighted imaging, with homogeneous contrast enhancement (Fig. 66-110).[367] Outside the CNS, chloromas may produce adjacent bone destruction and are often seen in the orbits, spine, paranasal sinuses, and the adjacent soft tissues,[367] as well as in the abdominal cavity (Fig. 66-111). Despite the uncommon presentation of this leukemic subset, extramedullary disease in any form—including that presenting without evidence of bone-marrow disease—is still considered evidence of systemic disease and is usually treated as such, with a combination of local control (surgery, radiation) and systemic chemotherapy.[368]

Lymphomas

Pediatric lymphomas are classified as either Hodgkin or non-Hodgkin lymphomas.[369,370] Because there is considerable overlap in the imaging features, age at presentation and sites of involvement are useful in helping to distinguishing the types of disease.[127]

Hodgkin Lymphoma

In Hodgkin lymphoma, the bulky mediastinal mass characteristically seen radiographically (Fig. 66-112) is made up primarily of inflammatory cells with the malignant Reed-Sternberg cell, from which the histologic diagnosis of Hodgkin lymphoma is made, comprising only 10% or less of the cells in the bulky lymph-node mass.[127] Hodgkin lymphoma is typified by involvement of contiguous lymph-node groups[371,372] and is staged according to the extent of lymph-node involvement in distinct nodal sites.

Staging. The most commonly used staging system is the Ann Arbor system (Table 66-5),[372,373] which involves determining the extent and pattern of lymph-node

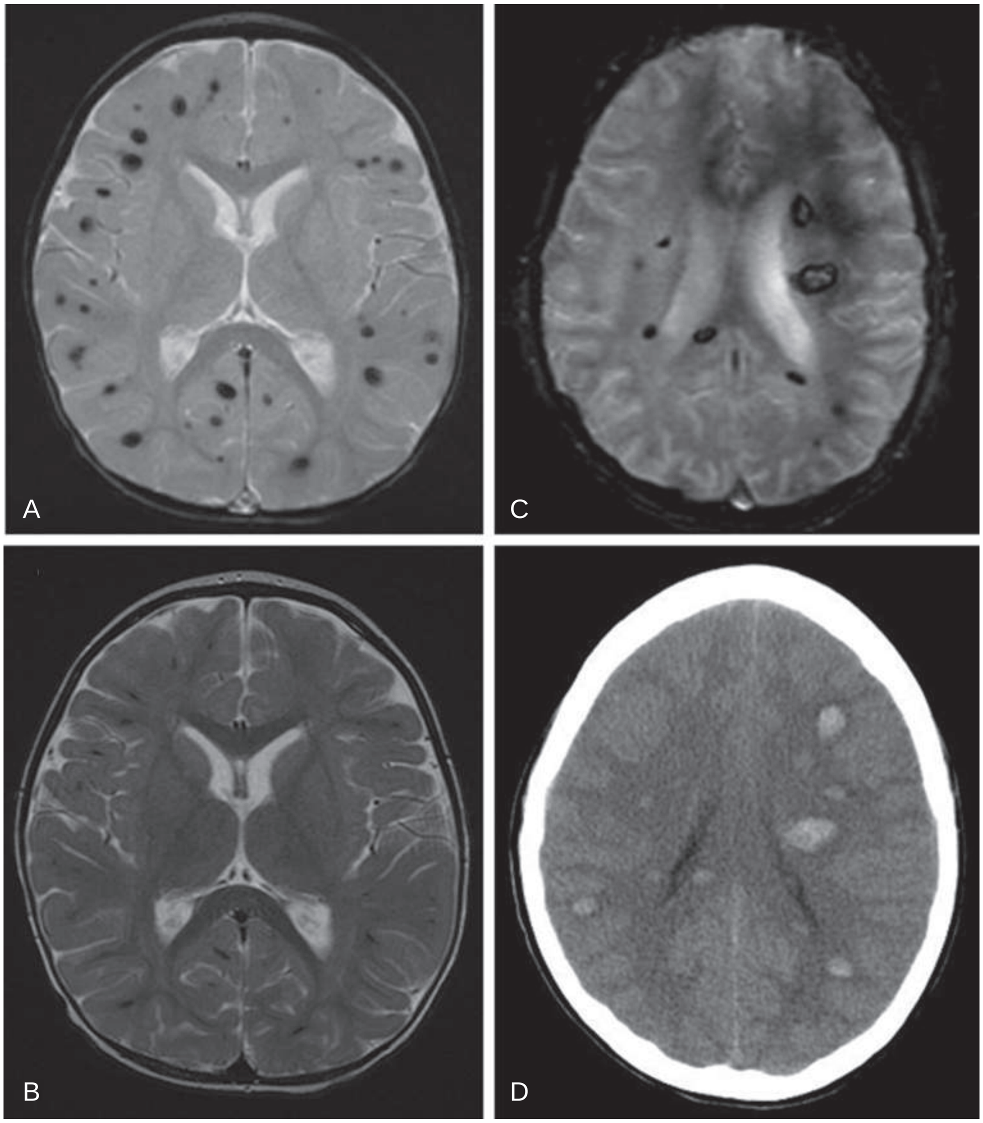

Figure 66-109 AML/APML. Gradient echo and FSE T2-weighted axial MRI images show the brain of a 17-month-old girl with AML who had a white blood cell count of greater than 300,000. Brain MRI obtained after the patient was stabilized showed multiple areas of paramagnetic susceptibility throughout the brain (**A**) with no corresponding T2 signal abnormality (**B**). Areas visualized were interpreted as foci of microthrombus formation secondary to leukostasis. A separate patient with APML had seizures, high white blood cell count, and a CT showing multiple foci of acute hemorrhage (**D**); the MRI showed multiple areas of paramagnetic susceptibility (**C**), likely caused by leukostasis with acute hemorrhage resulting from coagulopathy, reperfusion injury at sites of microthrombus formation, or both.

involvement. One unique feature of Hodgkin lymphoma relates to splenic involvement. For the purpose of disease staging, the spleen is consider localized lymphoid tissue, and lymphomatous infiltration of the spleen in Hodgkin lymphoma is not classified as stage 4 visceral metastatic disease, but rather as stage 3 disease.

The initial diagnosis is often prompted by chest x-ray evaluation for upper respiratory symptoms and vague constitutional symptoms such as fever and night sweats (see Fig. 66-112). At the time of diagnosis a mediastinal mass is encountered in more than two thirds of patients with Hodgkin lymphoma.[127,374] CT scanning is still the most commonly used cross-sectional modality for staging these patients. In addition to determining the extent of lymph-node involvement, pericardial and pleural effusions may be seen. Multiple sites of organ involvement may also be demonstrated, most commonly liver, spleen, and kidneys (Fig. 66-113). Children do not typically have symptoms referable to intraabdominal disease, so a thorough radiologic evaluation (intravenous and oral contrast-enhanced CT and FDG-PET) is essential to completely stage these patients. The staging evaluation for Hodgkin lymphoma should always include scanning of the neck to the level of the skull base in order to evaluate the nasopharyngeal and tonsillar lymphoid tissues (Waldeyer ring) for tumor involvement. Extensive involvement of the lymphoid tissue in Waldeyer ring may produce complete obliteration of the airway, requiring emergent intervention by a tracheostomy. As is true for all mediastinal lymphomas, the bulky anterior mediastinal mass

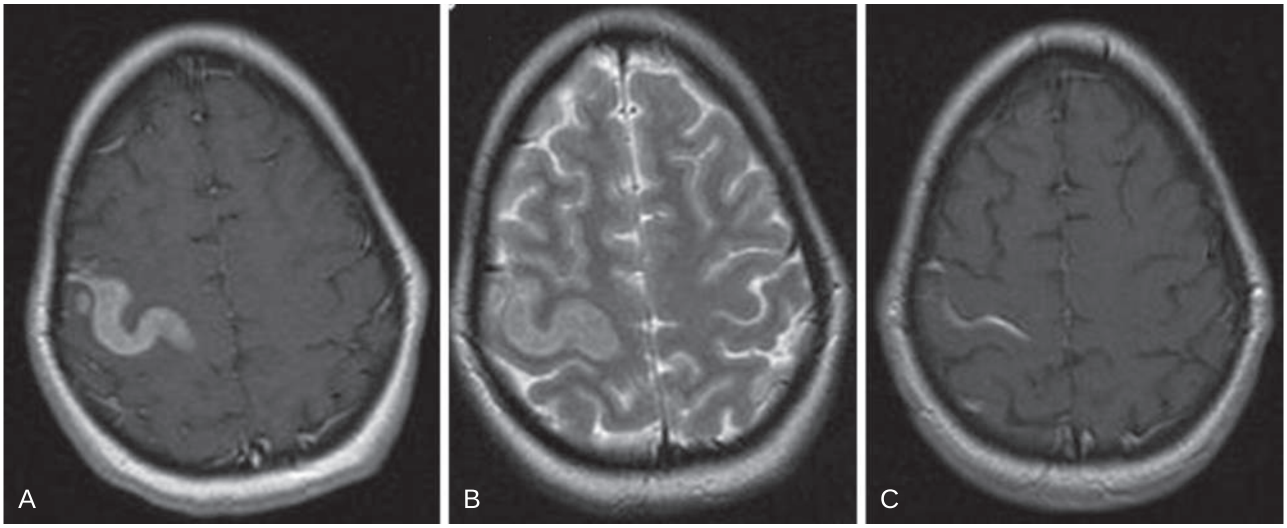

Figure 66-110 Chloroma in a 12-year-old patient with AML. Brain MRI shows typical findings of chloroma, including isointensity to cortex on T2-weighted images (**A**), homogeneous enhancement (**B**), and good response to radiation (**C**).

common in Hodgkin lymphoma may produce tracheal, bronchial, and central vascular compression (occasionally resulting in the superior vena cava [SVC] syndrome). Tracheal compression can result in acute airway compromise, particularly during procedures requiring general anesthesia and muscle relaxation. In addition, large anterior mediastinal masses can produce jugular vein thrombosis, venous sinus thrombosis, and CNS venous infarction (Fig. 66-114).

Pulmonary involvement in Hodgkin disease is unusual (seen in fewer than 5% of children under 10 years of age and fewer than 15% of adolescents),[374] but its identification often makes a difference in distinguishing stage 2 from stage 4 disease, resulting in dramatically different treatment regimens. Although pulmonary involvement can be quite extensive (Fig. 66-115), pulmonary nodules/masses that are associated with an ipsilateral hilar mass

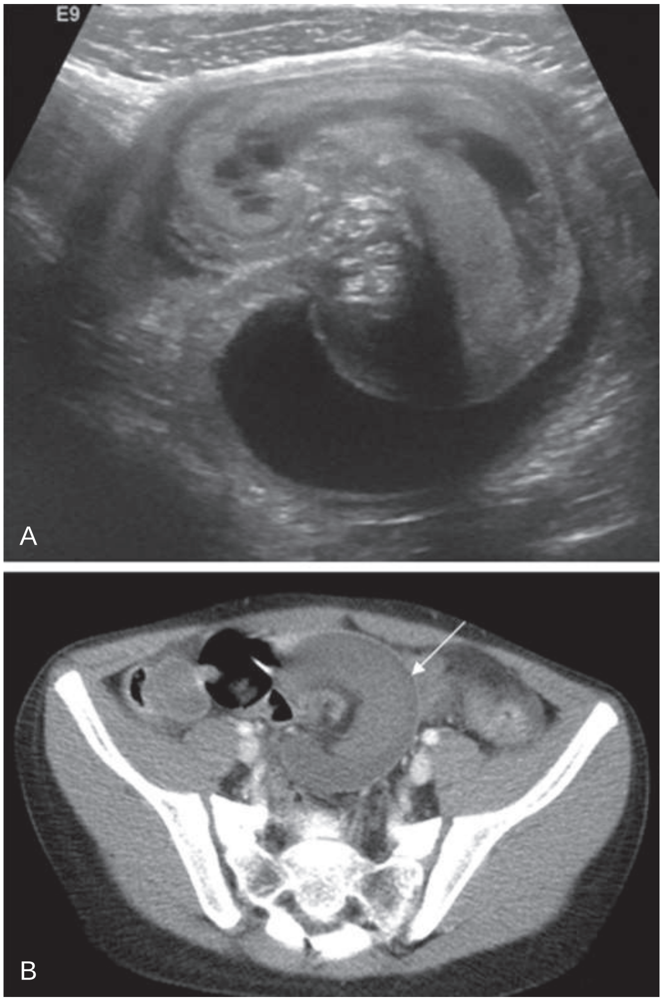

Figure 66-111 Extramedullary AML (chloroma). **A,** An 11-year-old boy with abdominal pain and vomiting had an ultrasound that revealed small-bowel intussusception. **B,** CT showed an abnormal mass involving the small bowel with apparent mural thickening *(arrow)*. At surgical resection this was found to be an isolated site of extramedullary AML (chloroma). The bone marrow biopsy was negative.

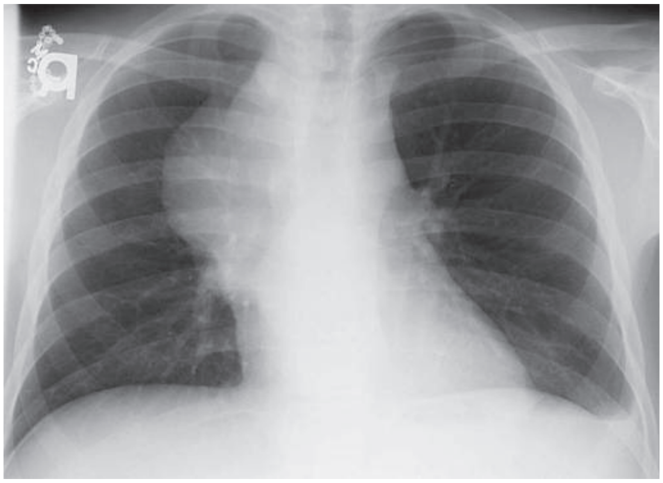

Figure 66-112 Hodgkin lymphoma. The chest x-ray of a patient with symptoms of a nonspecific upper respiratory infection shows an anterior mediastinal and paratracheal mass, as well as a small left effusion.

TABLE 66-5 Childhood Hodgkin Lymphoma: Ann Arbor Classification[372,373]

Tumor Stage	Description
1	Involvement of a single lymph node region, or Stage I(E): direct extension from that node to an adjacent extralymphatic region.
2	Involvement of two or more lymph node regions (number to be indicated) on the same side of the diaphragm, or Stage II(E): direct extension from any one of these lymph nodes to an adjacent extra-lymphatic organ.
3	Involvement of lymph node regions on both sides of the diaphragm. Stage III(E): may be accompanied by extension to an adjacent extralymphatic organ Stage III(S): may be accompanied by involvement of the spleen Stage III(E+S): involvement of both an adjacent extralymphatic organ and the spleen.
4	Noncontiguous involvement of one or more extralymphatic organs or tissues, with or without associated lymph-node involvement.

E, Extralymphatic spread of tumor into contiguous structures, to be distinguished from hematogenous spread; *S,* splenic involvement.

probably result in part from spread along peribronchial lymphatics,[371] although the distinction between local contiguous lymphatic spread and hematogenous dissemination can be challenging by CT.

As discussed in detail in the section on mediastinal masses, in addition to staging by CT, functional imaging with FDG PET is essential both for staging and monitoring response to therapy (see Figs. 66-31 and 66-32; Fig. 66-116). Historically, the time course to achieving gallium negativity was the initial functional imaging finding that correlated with event-free and overall survival.[375] However, with the ubiquitous use of FDG and modern day PET/CT scanners, gallium scintigraphy is rarely if ever performed for Hodgkin lymphoma.[135] FDG-PET imaging has been shown to impact staging and response assessment in a significant number of patients,* and its use in lymphoma has been incorporated into nearly all new clinical trials for Hodgkin lymphoma. As discussed earlier, there is growing evidence to suggest that early response to therapy, defined as rapid early resolution of previously FDG-avid sites of disease, even in the presence of residual disease by CT (see Fig. 66-32) or MRI, correlates with improved overall outcome.[144,149,378]

Using FDG-PET imaging to monitor changes in metabolic activity within the mediastinal mass provides an opportunity for making treatment decisions based on early response to therapy.[142,146] Based on studies in both adult and pediatric patients showing that patients with early metabolic responses to therapy have improved event-free and overall survival rates as compared with those who have residual PET abnormalities after the initial two cycles of therapy,[144,379] response-based treatment paradigms have been implemented clinically to directly test whether FDG-PET imaging is a reliable prognostic indicator for predicting chemosensitivity of the tumor and ultimately clinical outcome. Early results evaluating both change in size of the mediastinal mass and change in the metabolic activity have suggested that outcomes will likely be best predicted by a combination of factors, including resolution of FDG uptake and significant change in size of the patient's sites of disease involvement as measured by CT and/or MRI.[380,381] There have been no large multicenter prospective trials in either adults or children testing whether relying solely on FDG-PET to determine if early response to therapy can be used to reduce chemotherapy and radiation therapy in those patients achieving a rapid early response (reserving intensified treatment regimens for those patients not achieving an early response),[149,379] although one study reported a higher rate of early relapses in patients for whom involved-field radiation was omitted based on early resolution of FDG-avid disease.[382]

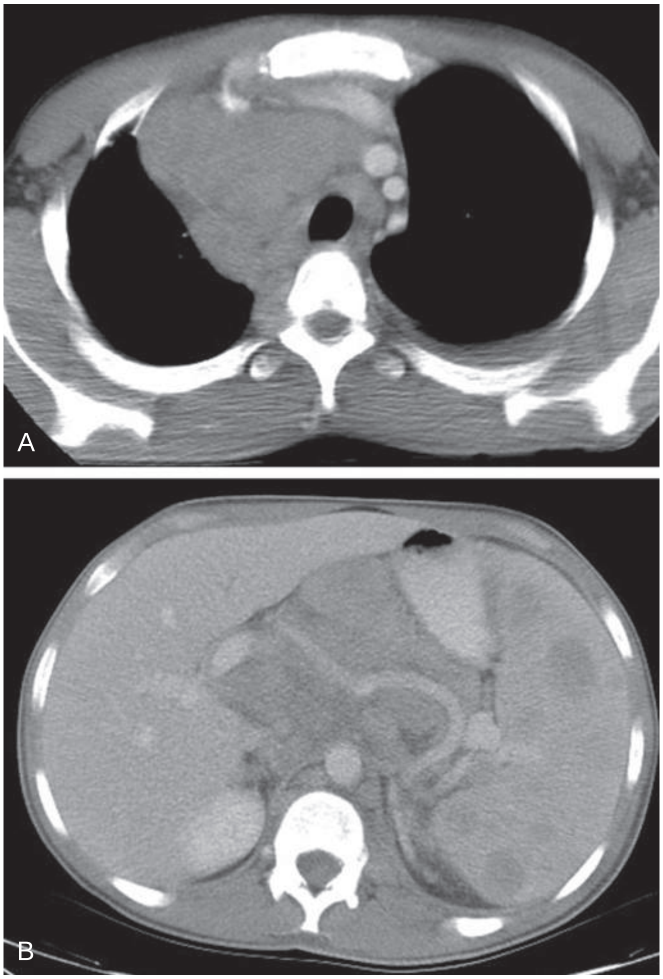

Figure 66-113 Hodgkin lymphoma. **A,** A contrast enhanced CT in patient whose chest x-ray is shown in Figure 66-112 shows the mediastinal mass and left pleural effusion. **B,** The images of the abdomen show extensive splenic, mesenteric, and retroperitoneal lymphadenopathy.

Given the importance of FDG-PET responses in dictating treatment decisions, an international team of experts reviewed the available data to arrive at the International Harmonization Project or International Working Group (IWG) consensus opinion regarding PET and CT criteria for determining disease and treatment response in lymphoma.[383,384] These are shown in Table 66-6, and are based on a revision of previous malignant lymphoma response criteria. Although the IWG criteria have not been validated in pediatric patients, the main challenge is developing objective standards for assessing FDG-PET response. A number of proposals have been suggested for distinguishing residual low-level neoplastic FDG activity from background uptake.[142] The use of SUV measurements is still considered experimental and has not been universally accepted. The Deauville Criteria—receiving the greatest acceptance—are based on a five-point scale, with uptake greater than mediastinal blood pool but less than liver, considered to be background, with uptake greater than the liver considered suspicious for residual

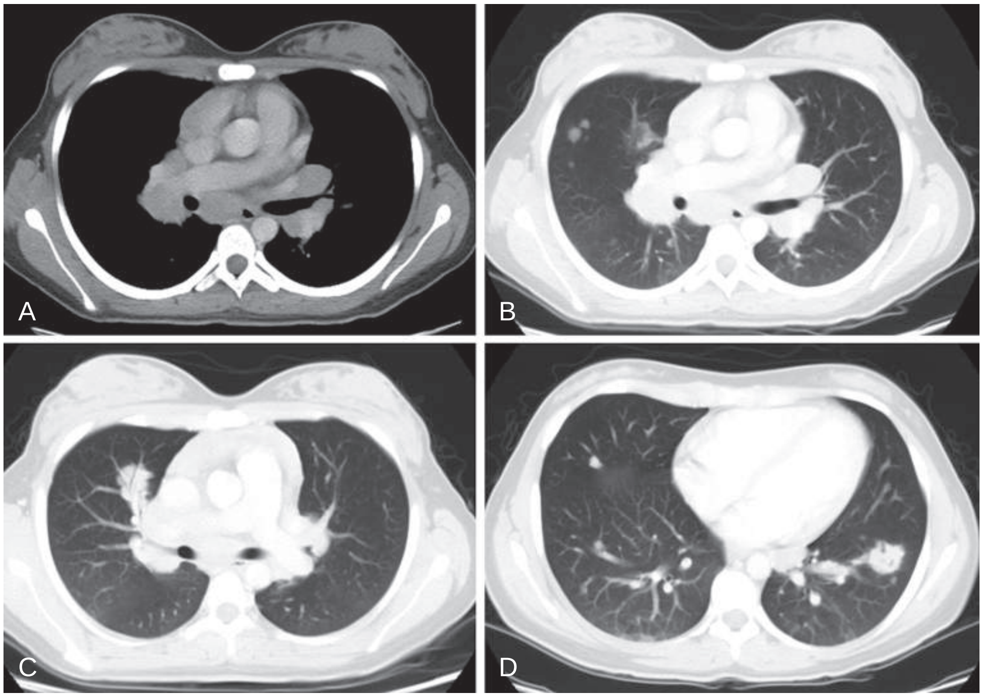

Figure 66-115 Hodgkin lymphoma and pulmonary involvement. This patient has extensive mediastinal and bilateral hilar nodal disease (**A**). The presence of discrete pulmonary nodules (**B** and **D**) may be the result of hematogenously spread disease, although contiguous spread along peribronchovascular lymphatics (**C** and **D**) is more common in Hodgkin lymphoma.

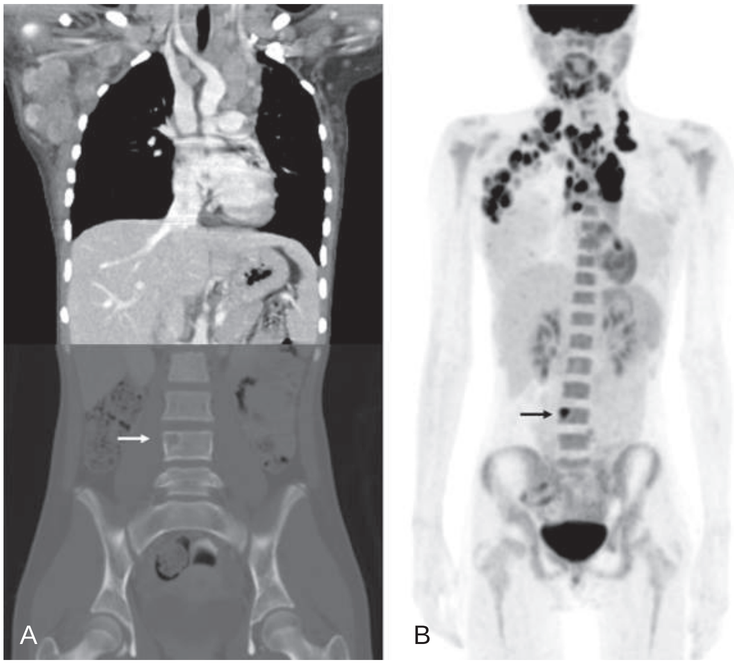

Figure 66-116 Hodgkin lymphoma and PET. Contrast-enhanced CT images of the chest, abdomen, and pelvis (**A**) show extensive mediastinal and axillary adenopathy, all of which is FDG avid. In addition, the PET scan (**B**) identifies a focus of FDG uptake at L4, corresponding to a subtle lytic lesion on CT, increasing the stage of this patient to stage 4. Note the background of low-level FDG uptake seen throughout the bone marrow, a common finding in Hodgkin lymphoma and reflective of a systemic inflammatory state associated with the disease rather an diffuse marrow infiltration.

metabolically active disease.[385] These criteria shown in Table 66-7 must be validated in larger treatment trials.

Non-Hodgkin Lymphomas

The non-Hodgkin lymphomas are a broad group of diseases.[127,370] Anaplastic large cell lymphoma often involves the soft tissues, skin, and bone, whereas Burkitt lymphoma most commonly presents with intraabdominal and mesenteric disease. Lymphoblastic lymphoma, particularly of the T-cell type, often presents with a mediastinal mass, although the appearance of the mass is characteristically distinct from the multilobulated bulky mass that is usually associated with Hodgkin disease. The distinction between T-cell lymphoblastic lymphoma and

TABLE 66-6 Summary of New International Working Group Criteria for PET and CT in Determining Response in Lymphoma[383]

Response	Criteria
CR*	FDG-PET completely negative. Residual lymph nodes/nodal masses allowed if FDG-negative. Bone marrow biopsy negative. Splenic/liver involvement must disappear. No new sites of disease.
PR	FDG positivity should be present in at least one previously involved site. Regression of measurable disease; no new sites of disease. ≥50% decrease in SPD of 6 dominant lymph nodes/nodal masses. ≥50% reduction in splenic/hepatic nodules, if present. Even if CR by other criteria, positive bone-marrow biopsy is considered PR.
SD	Failure to achieve PR, but not meeting PD criteria.
PD/Relapse	Any lesion increased in size by ≥50% from nadir. Any new lesion. PET should be positive in new/progressed lesions if ≥1.5 cm.

CR, Complete remission; *CT,* computed tomography; *FDG-PET,* 18-fluorodeoxyglucose positron emission tomography; *PD,* progressive disease; *PET,* positron emission tomography; *PR,* partial response; *SD,* stable disease; *SPD,* sum of the perpendicular diameters.

*New criteria include PET in definition of CR. PET considered positive if uptake is greater than mediastinal blood pool (lesions >2 cm) or above local background (lesions <2 cm).

TABLE 66-7 Five-Point Deauville Criteria for Determining FDG Response in Hodgkin Lymphoma[385]

Score	Semiquantitative Assessment of FDG Uptake
1	No uptake
2	Uptake less than mediastinal blood pool
3	Uptake greater than or equal to mediastinal blood pool but less than liver
4	Uptake greater than or equal to liver at any site
5	Markedly increased uptake at any site, including new sites of disease

FDG, Fluorodeoxyglucose.

TABLE 66-8 Childhood Non-Hodgkin Lymphoma: St. Jude (Murphy) Classification[386]

Tumor Stage	Description
1	A single tumor (extranodal) or nodal area is involved, excluding the abdomen and mediastinum.
2	Disease is limited to: A single tumor (extranodal) with regional node involvement, or Two or more tumors or nodal areas involved on one side of the diaphragm, or A primary gastrointestinal tract tumor (completely resected), with or without regional node involvement.
3	Tumors or involved lymph node areas occur on both sides of the diaphragm. Includes: Any primary intrathoracic (mediastinal, pleural, or thymic) disease Extensive primary intraabdominal disease Any paraspinal or epidural tumors
4	Tumors involve bone marrow (<25%) and/or central nervous system disease regardless of other sites of involvement.

its histologically-identical leukemic counterpart is made of the basis of bone-marrow aspirates; more than 25% marrow involvement results in a diagnosis of T-cell lymphoblastic leukemia.

Staging of non-Hodgkin lymphoma in most centers is according to the St. Jude Classification (Table 66-8).[386] Although there is considerable overlap in the imaging features of the lymphomas as shown in Figure 66-117, a localized anterior mediastinal mass that is not associated with other sites of significant contiguous lymph-node enlargement is more likely to be non-Hodgkin lymphoma. Non-Hodgkin lymphoma is also more likely to be disseminated at the time of diagnosis. Chest-wall and pericardial invasion is more common in the setting of non-Hodgkin lymphoma than in Hodgkin lymphoma (see Fig. 66-117).[370] The mediastinal mass in acute T-cell lymphoblastic lymphoma usually responds rapidly to chemotherapy, whereas other non-Hodgkin mediastinal lymphomas respond more slowly, with residual mediastinal abnormalities commonly seen even after multiple cycles of chemotherapy.

Non-Hodgkin lymphomas of the bone can present either primarily or in the setting of wide-spread metastatic disease. They often present with pathologic fracture and bone destruction[127] and may be difficult to distinguish from other processes.[387] MRI can be helpful in delineating the extent of marrow and adjacent soft-tissue involvement. Staging of non-Hodgkin lymphoma includes bone scintigraphy, which can be useful in distinguishing between localized osseous involvement and more widespread disease,[90] although it remains to be determined whether FDG-PET can replace bone scintigraphy in identifying sites of bone involvement in NHL.

Ileocecal involvement is common in non-Hodgkin lymphoma (Fig. 66-118). In the abdomen, intussusception in an older child should raise concern for a pathologic lead point caused by lymphoma. This is commonly seen in the setting of Burkitt lymphoma (see Figs. 66-67 and 66-118) but may also be seen in other forms of non-Hodgkin lymphoma.[127,370] The sporadic form of Burkitt lymphoma, which is more often encountered in Western and developed countries, is not etiologically linked to Epstein-Barr

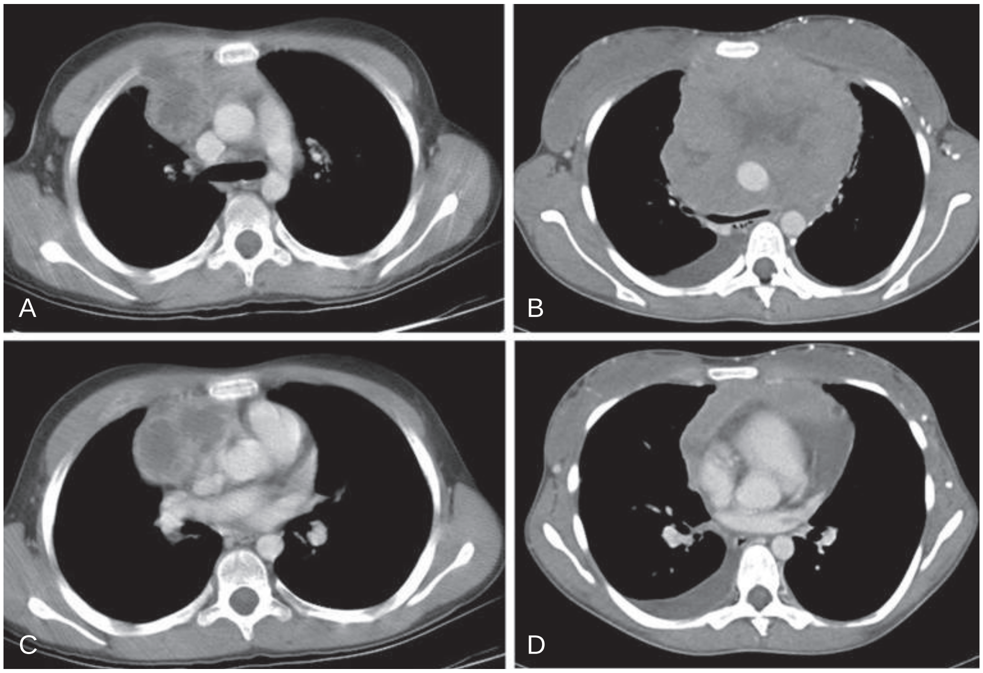

Figure 66-117 Non-Hodgkin lymphoma. Diffuse large B-cell (**A** and **B**) and B-cell–rich (**C** and **D**) non-Hodgkin lymphomas show chest wall and pericardial invasion that is more commonly seen in mediastinal non-Hodgkin lymphoma.

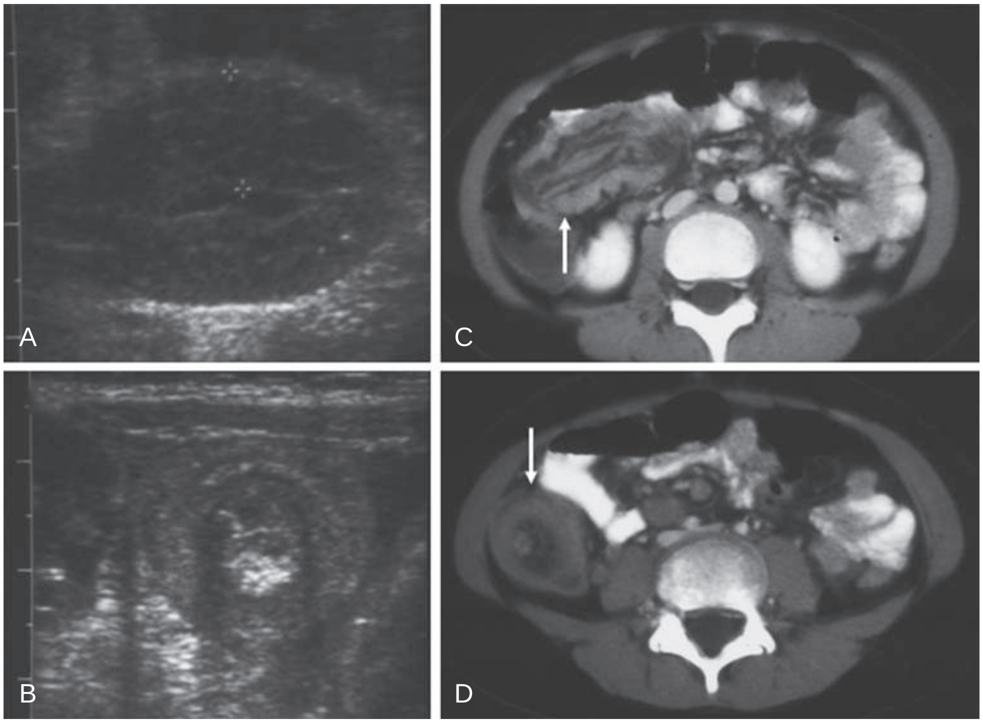

Figure 66-118 Non-Hodgkin lymphoma and intussusception. Ultrasound in a patient with Burkitt lymphoma (**A** and **B**) and CT in a patient with large-cell lymphoma (**C** and **D**) show typical features of intussusception, either small bowel/small bowel (**A** and **B**) or ileocolic (**C** and **D**).

virus (EBV) infection and has a pattern of bulky mesenteric and pelvic adenopathy, as well as involvement of multiple visceral organs including the liver, kidneys, and pancreas (see Fig. 66-64). Response of Burkitt lymphoma to chemotherapy is often quite rapid, with bulky disease responding within weeks. In contrast, the endemic form of Burkitt lymphoma, which is encountered in equatorial Africa, is usually associated with EBV infection (95%) and characteristically presents with jaw, orbit, paraspinal, and CNS involvement.[374]

Posttransplant lymphoproliferative disease (PTLD) is seen in the setting of both solid-organ and bone-marrow transplantation and results directly from the immunosuppression regimens used.[388] The lymphoproliferative disease, which is usually EBV-related, often responds to reduction in immunosuppression (Fig. 66-119). However, the lymphoproliferative disease may progress to an aggressive B-cell lymphoma, resulting in widespread malignant disease. PTLD can involve multiple organs and systems and responds variably to conventional lymphoma therapies. FDG-PET imaging is not routinely used in the management of PTLD, although some have advocated its use to improve early disease detection and staging.[389]

Just as with Hodgkin lymphoma, the role of FDG-PET imaging in non-Hodgkin lymphoma is currently being validated. Several studies of small cohorts of patients have indicated that FDG-PET is valuable both for staging and for predicting response to therapy in patients with

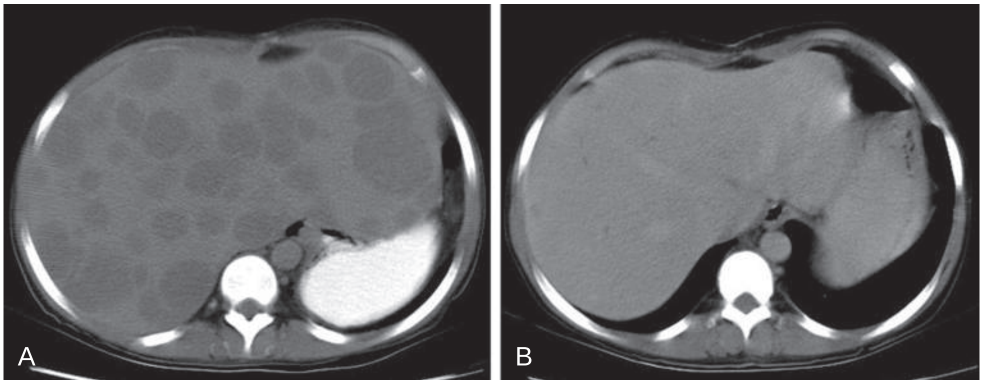

Figure 66-119 A 22-year-old patient with a renal transplant developed extensive PTLD involving the liver (**A**). **B**, Four months after reducing the immunosuppressive therapy, the PTLD had nearly completely resolved.

various forms of NHL.* As suggested by these studies, FDG-PET, particularly when combined with cross-sectional imaging either by CT or MRI, is extremely sensitive at detecting sites of disease that may not have otherwise been identified. It seems obvious that identifying the extent of disease should impact both staging and monitoring of treatment response; however; prospective trials are needed to determine whether FDG-PET response alone can by used to direct response-based modulation in therapy.

Sites of Relapse in Hematologic Malignancies

In the treatment of leukemia and lymphoma, radiologic evaluation plays an important role in monitoring for disease relapse. In addition to intramedullary (i.e., bone-marrow) relapse, common sites of extramedullary leukemic relapse include kidneys, spleen, CNS, and bone. Although less common, relapse to “sanctuary sites” such as the testicle can occur, both with diffuse organ infiltration and enlargement and with focal mass deposits (Fig. 66-120). Relapse to these sites may occur even in the setting of bone-marrow remission.

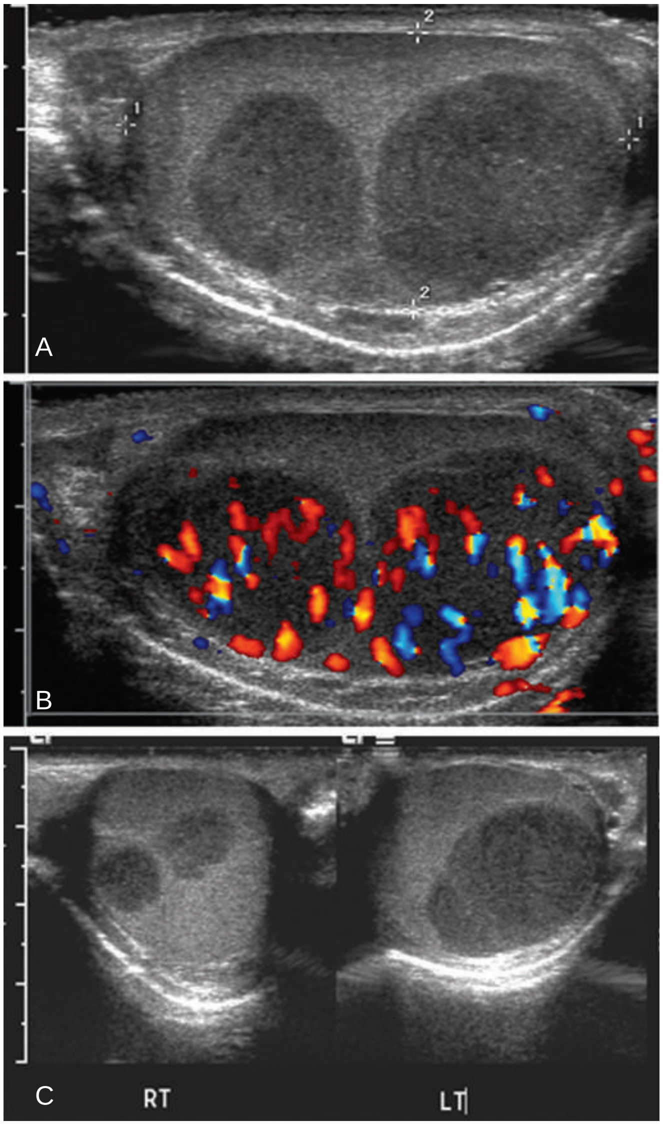

Figure 66-120 Scrotal relapse of leukemia. A 17-year-old patient with high risk ALL, s/p bone marrow transplant had painless scrotal swelling and palpable abnormalities on exam. Scrotal ultrasound shows multiple bilateral hypoechoic masses (**A** and **C**) (relative to testicular parenchyma) with increased blood flow to the masses (**B**), diagnostic of scrotal relapse.

IMAGING TREATMENT COMPLICATIONS

Complications resulting from the treatment of pediatric malignancies are myriad. It is important to note that the radiographic manifestations of fungal and other infectious diseases may not be manifest during periods of profound neutropenia (Fig. 66-121). Often, abnormalities on imaging studies emerge only after peripheral neutrophil counts recover and infection-fighting white blood cells become available to mount an inflammatory response. Infectious complications commonly include localized as well as disseminated fungal infection. The extent of hepatic and splenic involvement may be better detected by MRI (Fig. 66-122).[394]

Cardiomyopathy results from cardiotoxic chemotherapy agents such as doxorubicin. Echocardiography has become the imaging modality of choice in monitoring patients with this complication. Pulmonary toxicity can range from subtle ground-glass opacity, which can be an early manifestation of bronchiolitis obliterans with organizing pneumonia (BOOP, or cryptogenic pneumonia) to frank interstitial pulmonary fibrosis.[395]

Children with cancer also have poorly understood hypercoagulable state. Pulmonary emboli and other sites of venous thrombosis occur at an increased incidence in these patients and may be detected either incidentally (Fig. 66-123) or in response to specific clinical symptoms.[396] Clinically the probability of thromboembolic disease may be difficult to assess. The presence of multiple known risks factors, including indwelling catheters, concurrent infection, immobility, dehydration, and chemotherapy all increase the risk of thromboembolic events in these patients,[397] and the clinician and radiologist must be vigilant in their respective examinations to enable early detection and treatment of these potentially live-threatening complications.

Gastrointestinal complications occur during periods of neutropenia and can range from typhlitis (with localized inflammation of the cecum) to extensive pancolitis and bowel necrosis (Fig. 66-124).[398,399] Asparaginase, which is included in many chemotherapy regimens for ALL and lymphoblastic lymphoma, results in pancreatitis in approximately 5% to 10% of patients. The severity of pancreatitis can range from a mild chemical pancreatitis to frank pancreatic necrosis and subsequent pseudocyst formation (Fig. 66-125). This is best evaluated initially by ultrasound, with CT reserved for persistent or worsening clinical pancreatitis or to assess for complications such as pseudocyst.[400]

---

*References 134, 136, 150, 246, 247, 390-393.

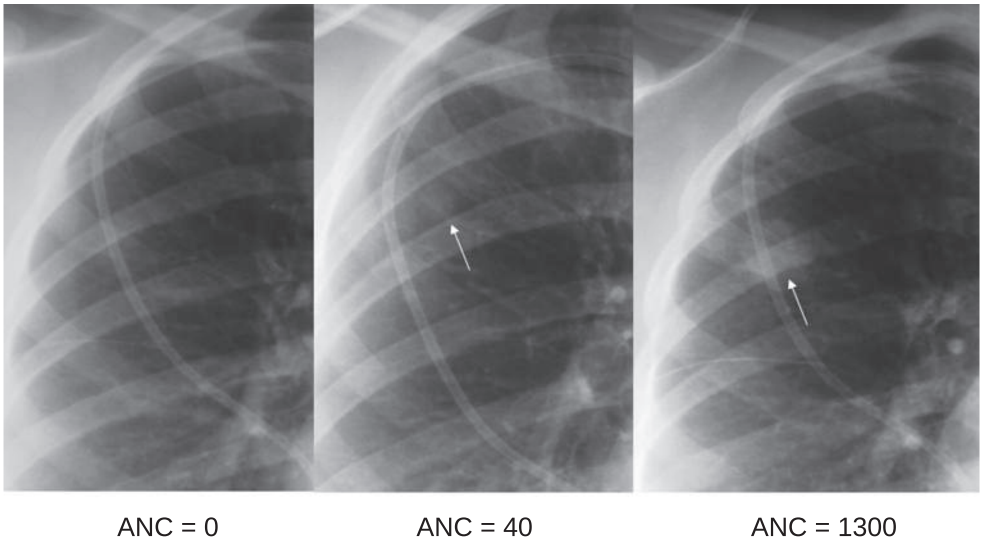

Figure 66-121 Imaging the patient with neutropenia. X-rays are of a 12-year-old patient with AML. Note the appearance of focal lung nodule *(Aspergillus)* as the patient's blood cell counts recover, suggesting that the appearance of infectious lesions in patients with neutropenia may be challenging to detect until the marrow has recovered after ablative chemotherapy.

Bony complications can arise after chronic treatment with corticosteroids and include osteopenia, fractures, bone-marrow infarcts, and osteonecrosis (Fig. 66-126), the latter of which is most typically seen in the hips and knees.[401] Second tumors, particularly musculoskeletal tumors, may be seen after radiation therapy. Osteochondromas involving the clavicles and sternoclavicular junction, for example, are common in patients with lymphoma who have received mantle radiation, particularly if radiation occurred at an early age. Malignant degeneration of these lesions is rare.

CNS changes can develop after radiation and chemotherapy. In one study, hemorrhagic events were seen in 4 of 120 children with ALL. All of these children had been disease-free for more than 2 years and had been treated with prior chemotherapy and cranial radiation.[402] These events are most commonly related to treatment-induced vasculopathy and may show diffuse or localized vasculopathy. Asparaginase may also produce venous sinus thrombosis, leading to profound neurologic deficits and areas of venous infarction (Fig. 66-127). Methotrexate, which is given both systemically as well as intrathecally for CNS prophylaxis in patients with high-risk ALL, may produce a leukoencephalopathy characterized by symmetric periventricular white-matter signal abnormalities. These changes may be transient or permanent. They are not specific to methotrexate and can be seen with other chemotherapeutic agents that penetrate the CNS.

Patients treated for cancer in childhood are also known to have an increased risk of developing second malignant neoplasms as a result of both cytotoxic chemotherapy and radiation therapy. In reports from the Childhood Cancer Survivor Study (CCSS), there was a 2.3-fold increase in second malignant neoplasms in children treated previously for cancer,[403] with patients who had Hodgkin lymphoma or Ewing sarcoma at greatest risk

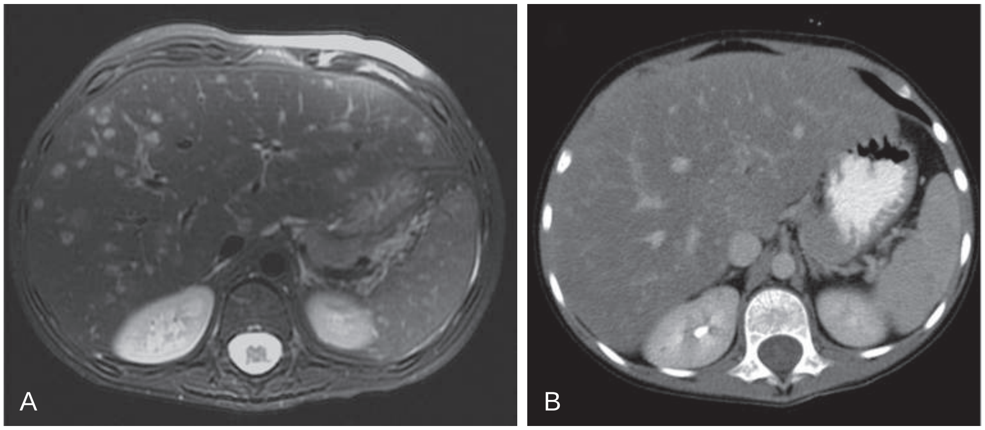

Figure 66-122 Imaging hepatosplenic fungal infection. MRI using fluid-sensitive FSEIR (or similar) sequences (**A**) is very sensitive for detecting lesions not seen with CT (**B**) or ultrasound.

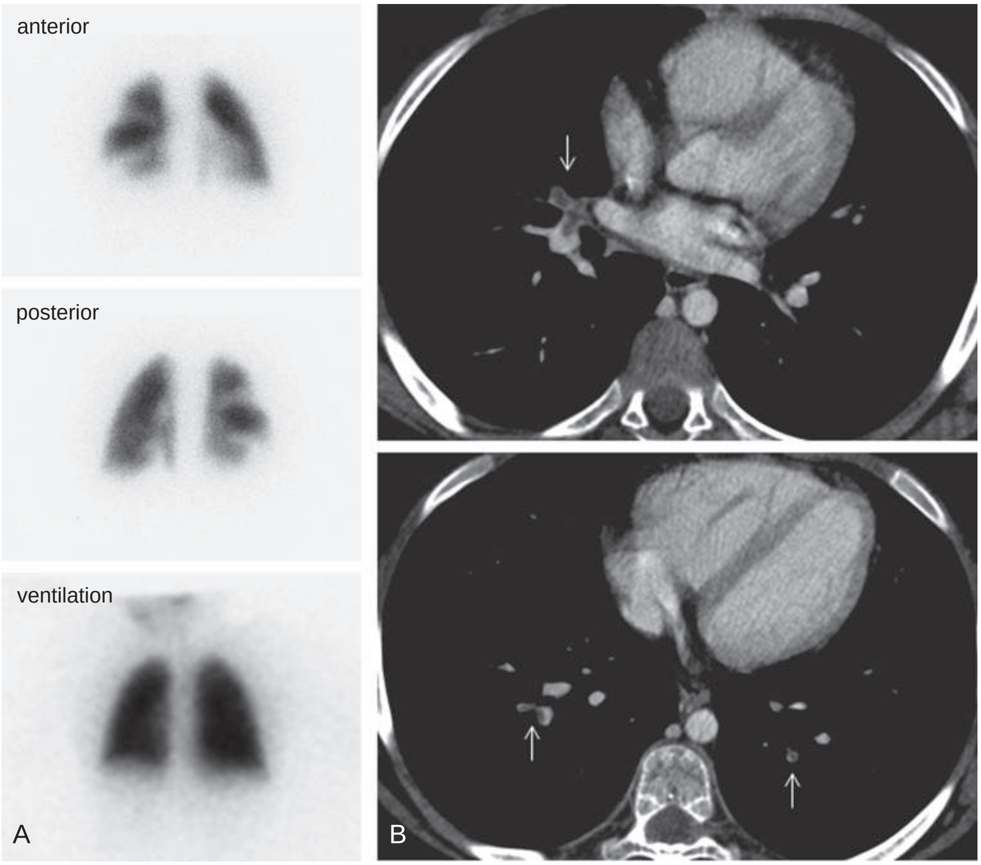

Figure 66-123 Pulmonary emboli. A 6-year-old boy with T-cell ALL had fever and neutropenia. CT scan of the chest identified multiple pulmonary emboli involving multiple lung segments (**B**). CT findings were confirmed by ventilation/perfusion scanning (**A**), which demonstrated multiple perfusion defects corresponding to involved segments identified by CT, but no corresponding ventilation defects.

(Fig. 66-128).[404] The most common second cancers include bone, breast, and thyroid cancer, as well as tumors of the CNS (meningioma and glioma) (Fig. 66-129).[405]

INTERVENTIONAL RADIOLOGY IN PEDIATRIC ONCOLOGY

Pediatric interventional oncology, also known as the "fourth pillar of cancer treatment" is an emerging specialty that offers an alternative resource when other options like surgery, chemotherapy, or radiation therapies have limited usefulness. This primarily involves use of minimally invasive techniques with image guidance for directly targeting tumors, both for diagnostic and for therapeutic reasons. When considering "tumors" broadly, to include nonneoplastic growths, pediatric interventional radiologists are involved in all aspects of management from diagnosis to treatment to offering palliative care. With regard to neoplastic disease, oncology-related pediatric interventional radiological procedures have traditionally been limited to diagnosis, management of complications, and procedures designed as auxiliaries to open surgery. Because of limitations such as the approval process for new devices, protocol-driven pediatric oncologic practice, and the inherent hesitation of trying new treatments in children, the development of interventional oncology for children has been challenging.[406] Newer landmarks in pediatric therapeutic oncological interventions are under active development, but standards remain to be established. Although many broad principles in adult and pediatric interventions are the same, some specific aspects related to procedures in children deserve discussion, and are enumerated in the following list.

1) Informed consent: Because most pediatric patients younger than 18 years of age have parents or legal guardians, a detailed preprocedural discussion is necessary to educate them regarding possible complications, some of which may remain present throughout life. Many adolescent patients are able to participate actively in the decision-making process. This usually requires a detailed conversation that is simple, clear, and addressed in a way to make the parents and the child comfortable without inducing unwarranted fear of the procedural risks. It is appropriate to create a "child-friendly environment" to provide a sense of safety, security, and dedicated pediatric care.
2) Sedation and anesthesia: Almost all the procedures in children need general anesthesia or higher levels of sedation to minimize motion, help children tolerate pain better, and allow positioning during the

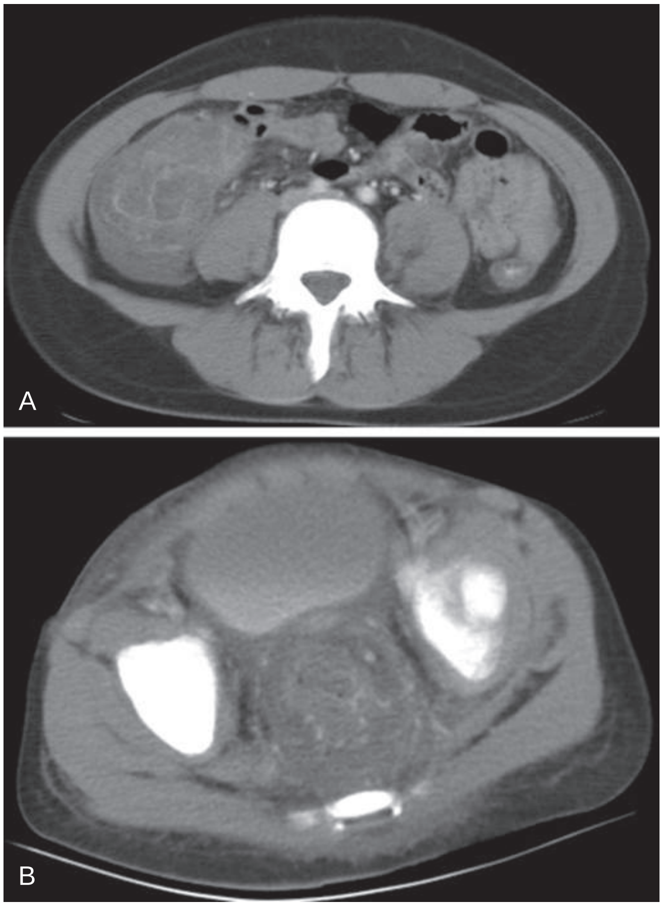

Figure 66-124 Contrast-enhanced CT in two patients with neutropenic colitis, showing disease primarily of the terminal ileum and cecum; i.e. typhlitis (**A**) and more extensive pancolonic disease with severe rectal necrosis that required diverting ileostomy (**B**).

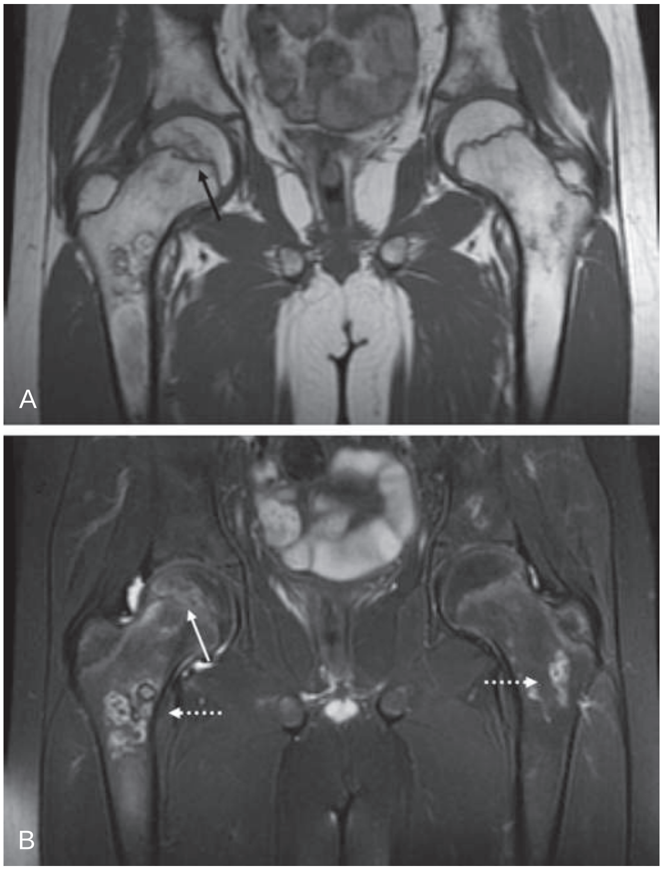

Figure 66-126 Osteonecrosis/avascular necrosis. A 13-year-old patient with a history of high-risk ALL, receiving high dose steroids, experienced right hip pain. Unenhanced T1-weighted (**A**) and Gd-enhanced (**B**) MRI of the hips and pelvis show osteonecrosis of the right femoral head *(arrows)* and evidence of bone infarcts in both femoral necks *(dashed arrows)*.

procedure. Deep sedation or general anesthesia can provide some postprocedural amnesia, unlike adults who can tolerate most procedures under mild sedation and local anesthesia.

3) Equipment: Most available devices are designed for use in adults. Hence bench modifications of devices developed for adults are often performed to match the smaller body habitus of children.
4) Contrast and radiation: It is imperative that contrast doses be diligently monitored in children to minimize renal toxicity. Likewise, maximal efforts are directed to limit the radiation dose, because the cumulative effects of radiation are of major concern in children. Most interventional radiologists practicing in adult populations concern themselves largely with the deterministic effects of radiation

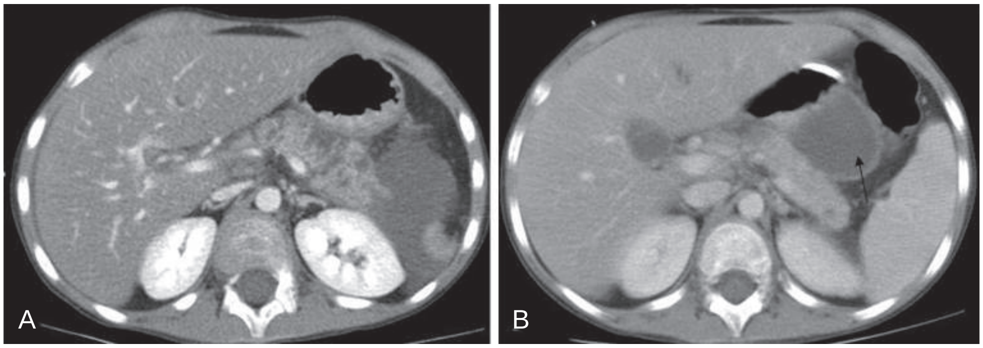

Figure 66-125 An 11-year-old with ALL receiving asparaginase developed severe pancreatitis (**A**) and subsequent pseudocyst formation *(arrow)*, with the pseudocyst closely adherent to the posterior wall of the stomach (**B**).

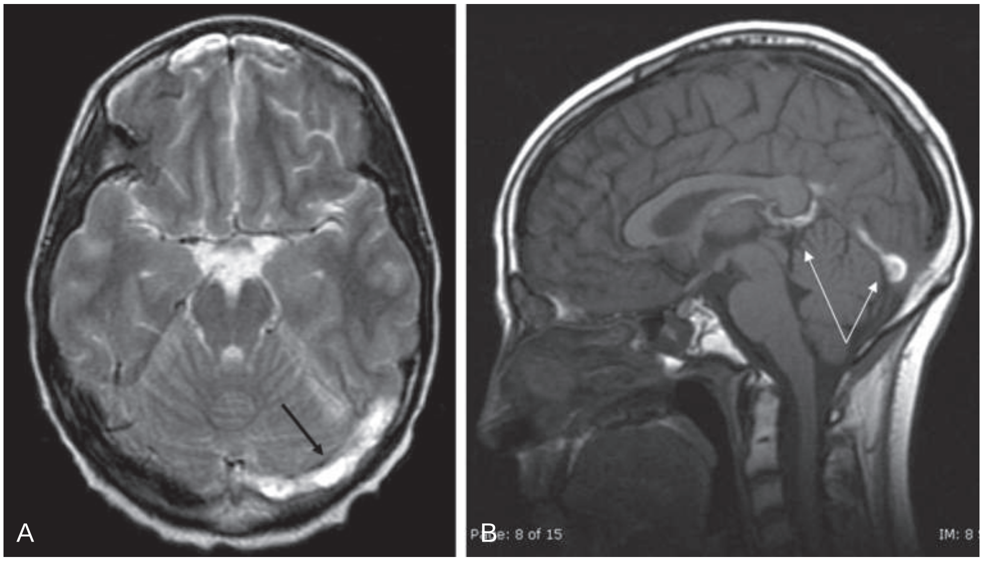

Figure 66-127 Cerebral sinus thrombosis. Axial T2-weighted (**A**) and sagittal T1-weighted (**B**) MRI in a 15-year-old patient with ALL, receiving asparaginase during induction therapy, shows high signal-intensity abnormality in the left transverse sinus, straight sinus, and deep cerebral veins *(arrows)*.

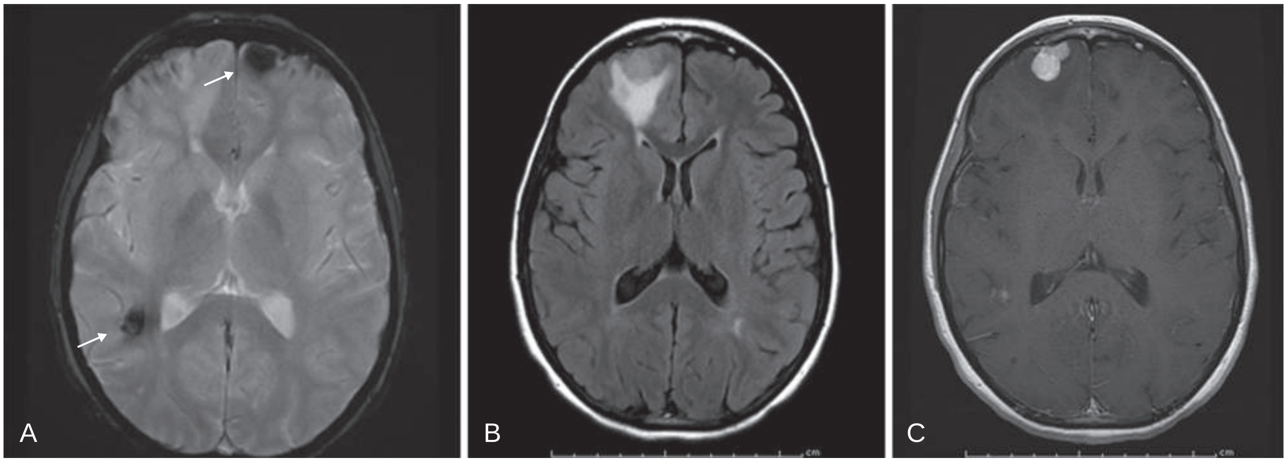

Figure 66-128 Radiation-related change and second malignancy. A 22-year-old patient was treated for ALL as a child with chemotherapy and craniospinal radiation therapy. Known cavernous angiomas (**A,** *arrows*) were being monitored routinely. She experienced seizures, and a new right frontal-lobe lesion seen on T2-FLAIR (**B**) and contrast-enhanced T1-weighted (**C**) MRI was found on resection to be high-grade sarcoma, presumably related to prior radiation.

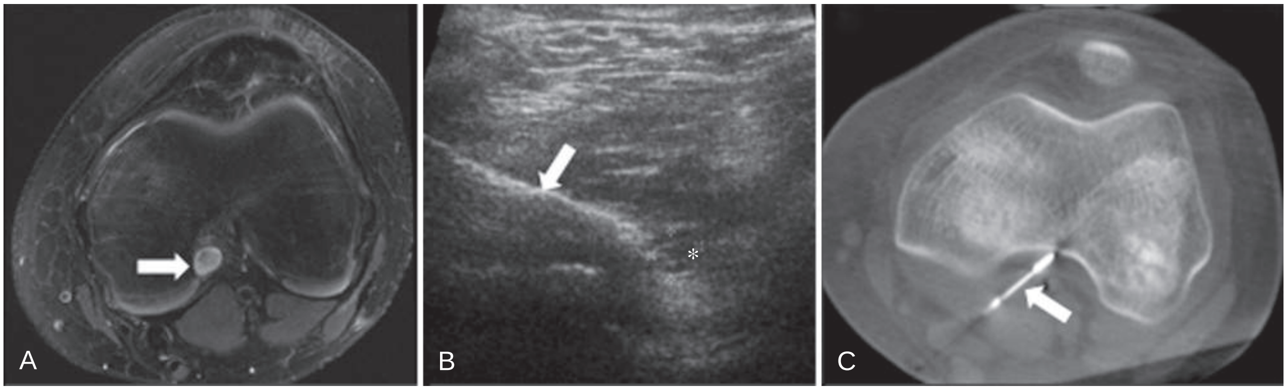

Figure 66-129 Percutaneous image-guided core needle biopsy. **A**, Axial T2-weighted fat inversion recovery MRI demonstrating a painful focal solid mass situated deep into the intercondylar notch of femur *(arrow)*. **B**, Ultrasound-guided access of the nodular lesion *(asterisk)* with a coaxial needle *(arrow)* **C**, Dyna CT images demonstrating the biopsy needle deployed into the lesion *(arrow)* to obtain samples.

related to dose and time of exposure at the time of the procedure. These effects are usually manifest as damage to bone marrow, gastrointestinal mucosa, or skin. It is, however, the stochastic effects, those cumulative effects that are related to any exposure to ionizing radiation regardless of time or dose, that are far more concerning in the pediatric population than the adult.[407]

There is no minimum threshold radiation dose for stochastic effects to occur, and stochastic exposure (primarily related to DNA damage) may not manifest itself for decades. It is specifically in young children with many years of life ahead that these issues are of greatest concern. Additionally, many oncology patients are exposed to high-dose external-beam radiation as part of their treatment protocol, adding to the risk. The ALARA concept of radiation exposure is ubiquitous in radiology but is held to much higher standard in pediatric diagnostic imaging and pediatric interventional radiology, with risk of radiation exposure always weighed against the benefits of a given image-guided procedure, and every attempt is made to use the lowest possible radiation dose. Limiting the fluoroscopy time, low-dose pulse fluoroscopy, aggressive coning and filtering applied to the smallest possible region of interest, and maximal utilization of imaging modalities that are nonionizing are used to reduce radiation exposure.

5) Anatomic considerations: Children have a smaller body mass index, which can limit accessibility. In compact regions like the neck, continuous image guidance using ultrasound imaging or CT fluoroscopy is preferred during biopsies to avoid major blood vessels and nerves. In children these procedures are done with the use of general anesthesia, which may obscure immediate signs of nerve injury. Because of the smaller volume of subcutaneous fat and muscle bulk, the skin can be also vulnerable to injuries during ablation of tumors. These aspects of the procedure must be carefully considered during preprocedure planning.
6) Physiologic responses: Physiologic responses to intervention can be different in a child versus an adult. For example, vasospasm is commonly seen in children, making simple access or further intravascular manipulation more challenging. Children react to fluid imbalances and medications more quickly. Therefore close monitoring of fluid balance and drug dosages based on weight or body-surface area is mandatory; vigilant care on the part of specialized pediatric nurses and a pediatric anesthesia team is invaluable.

Role of Interventional Oncology

Generally, oncological interventions depend on the kind of care that is provided. This can be divided into the following areas: 1) diagnostic evaluation; 2) therapeutic care; and 3) supportive and palliative care.

Diagnostic Evaluation

Percutaneous Needle Biopsy

Core biopsy can provide tissue both for accurate histopathology, immunohistochemistry, and molecular pathology necessary for diagnosis and differentiation of childhood tumors. In some tumors like neuroblastomas, biopsy provides tissue not only for histologic classification but also for analysis of prognostic factors, such as *MYCN* and ploidy status.[408] Almost any mass can initially be biopsied using image-guided percutaneous needle biopsy. Ultrasound guidance is usually the imaging modality of choice given its real-time capability. Most biopsy needles are sonographically visible, and precise real-time targeting of most masses is possible, even in locations adjacent to vital structures (see Fig. 66-129). Other guidance modalities can be used for targeting, including CT and MR; these typically require general anesthesia. These authors often use Dyna CT with the I-guide technology to target areas situated in critical or compact zones (Fig. 66-130). Correlation with MRI or FDG-PET can guide the targeting to viable segments of tumor.

Evaluating tissues located in prior operative sites or within radiation fields can be challenging diagnostically

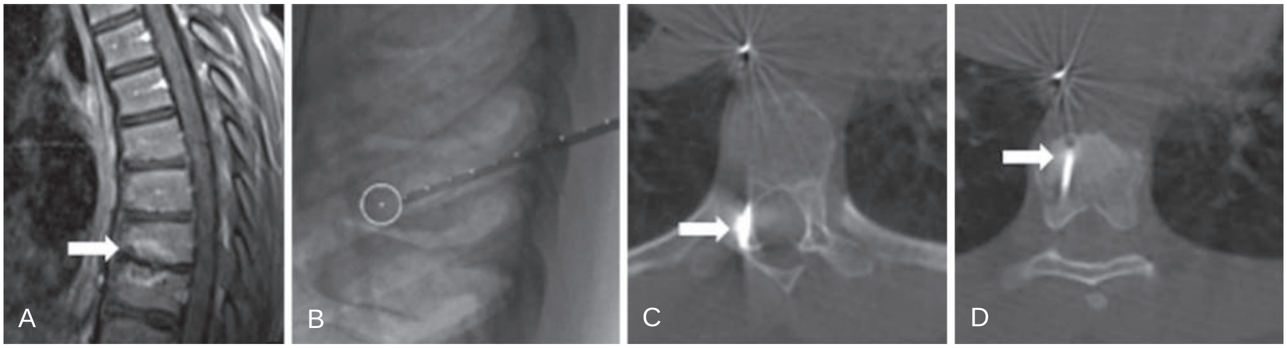

Figure 66-130 Percutaneous image-guided core needle biopsy. **A**, Sagittal T1-weighted contrast enhanced MRI of the spine demonstrating an enhancing destructive lesion of contiguous vertebral endplates *(arrow)*. **B**, The more destructive of the endplates was targeted using the I-guide technology *(circle)* on Dyna CT. **C**, Transpedicular course *(arrow)* of the biopsy needle is seen on the Dyna CT image. **D**, The biopsy needle tip is safely positioned at the proposed biopsy site *(arrow)*.

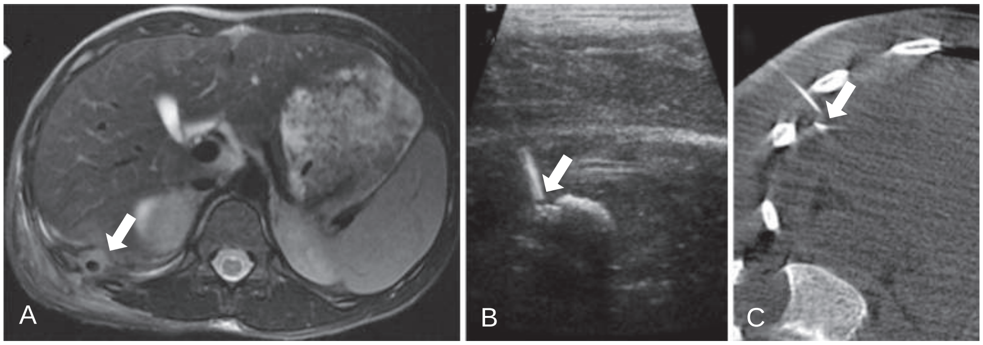

Figure 66-131 Needle localization. **A**, Axial T2 MRI of the abdomen demonstrating a hypointense, likely calcified, subhepatic nodule causing intense perilesional inflammation. An image-guided needle localization of this was requested before surgical exploration. **B**, Ultrasound-guided access toward the lesion *(arrow)* was performed. **C**, A hook was deployed *(arrow)* at the nodule to help localize the lesion at surgery as seen on Dyna CT image.

and can also be difficult to access, particularly when situated deep to vascular, neural, and bony structures. A multiple quadrant sampling or targeted sampling of FDG-avid areas should be planned, because intratumoral histologic heterogeneity could result in sampling artifacts that lead to incorrect prognostic histologic subgroup assignment,[408] which in turn may impact therapy. The most commonly biopsied structures include liver, renal and suprarenal tumors, mediastinal tumors, musculoskeletal tumors with associated soft tissue, and bony masses.

Obtaining a sample from the soft-tissue mass, bone mass and its interface is most helpful. Automated or semiautomated cutting needles in the range of sizes between 14-gauge and 20-gauge are available providing 1- to 2-cm throws. A coaxial core-needle biopsy technique is used, in which an initial puncture of the skin and the tumor capsule is made using a needle mounted on a coaxial outer cannula. A 16- or 18-gauge cutting needle (manual or spring-loaded) is then advanced via this outer cannula into the lesion, and several samples are obtained aiming at different tumor quadrants. This technique theoretically reduces the chance for tract seeding and also the possibility of bleeding and infection by limiting the number of punctures. Using the coaxial needle also allows the biopsy tract to be embolized if bleeding does not stop spontaneously or in patients with poor coagulation. For bone biopsies an 11- or 13-gauge needle permits the coaxial passage of a trephine Ackermann needle (Cook Medical, Bloomington, Ind.) to complete the bone biopsy. Smaller coaxial systems such as the Bonopty biopsy needle (Radi Medical Systems, Uppsala, Sweden) (12 and 14 gauge) are also available. Bony drills can be employed to obtain deeper access or access very hard bony lesions. Risks are smaller and rare and include bleeding, infection, and injury to the structures around the target.

Very tiny lesions or anatomically arduous areas can be subjected to fine-needle aspiration. Fine-needle aspiration can be obtained using a 20- to 22-gauge needle placed independently or coaxially via an 18- to 19-gauge needle. Whenever possible, the shortest and safest course to reach the lesion should be chosen. Accuracy, less invasiveness, low rate of complications, shorter recovery time, and ability to do targeted and multiquadrant sampling through minimal number of accesses are some of the major benefits of image-guided percutaneous biopsies.[409-412] Available pooled data suggests that 95% of image-guided needle biopsies provide adequate sample for tissue diagnosis in childhood malignancies.[413] CT or sonography can be used preoperatively, using similar technique as for biopsy, to place Kopans localization hook wires (Cook Medical, Bloomington, Ind.) (Fig. 66-131) or coils or to inject a dye to help the surgeon easily find the lesion during operation.[414] The interventional radiologist also has the ability to place central venous lines or chemotherapy ports as part of the same interventional radiological procedure, precluding the need for a separate operating room visit and additional anesthesia.

Therapeutic Care

Therapies providing local control of tumors are widely used in adult interventional oncology practice. Indications for regional cancer treatments in children are still evolving and are based largely on experience extrapolated from the adult literature. These can be categorized broadly based on their principle of use: 1) transarterial embolization; 2) tumor ablation; 3) high intensity focused ultrasound; and 4) irreversible electroporation.

Embolization Therapy

This technique involves performing catheter angiography to determine the arterial perfusion to the tumor. After this, feeding vessels are selectively catheterized to deliver tumoricidal drugs or to create tumor ischemia by stopping the blood flow in these vessels.

Chemoembolization. This is also known as *transarterial chemoembolization (TACE)* in which chemotherapy is delivered by injecting a mixture of the chemotherapeutic agent with Ethiodol or particles, or as chemotherapeutic agent-impregnated beads, also known as *drug-eluting beads (DEBs)*. This technique concentrates the chemotherapy drug in the target tissues, with the embolization effectively prolonging the dwell time of the agent in the target with less systemic effect than intravenous or oral chemotherapy. In adults TACE has been widely used for hepatocellular carcinoma and hepatic colonic metastases. It has significantly prolonged 2-year survival rates up to 63% as compared to 27% with supportive care.[415]

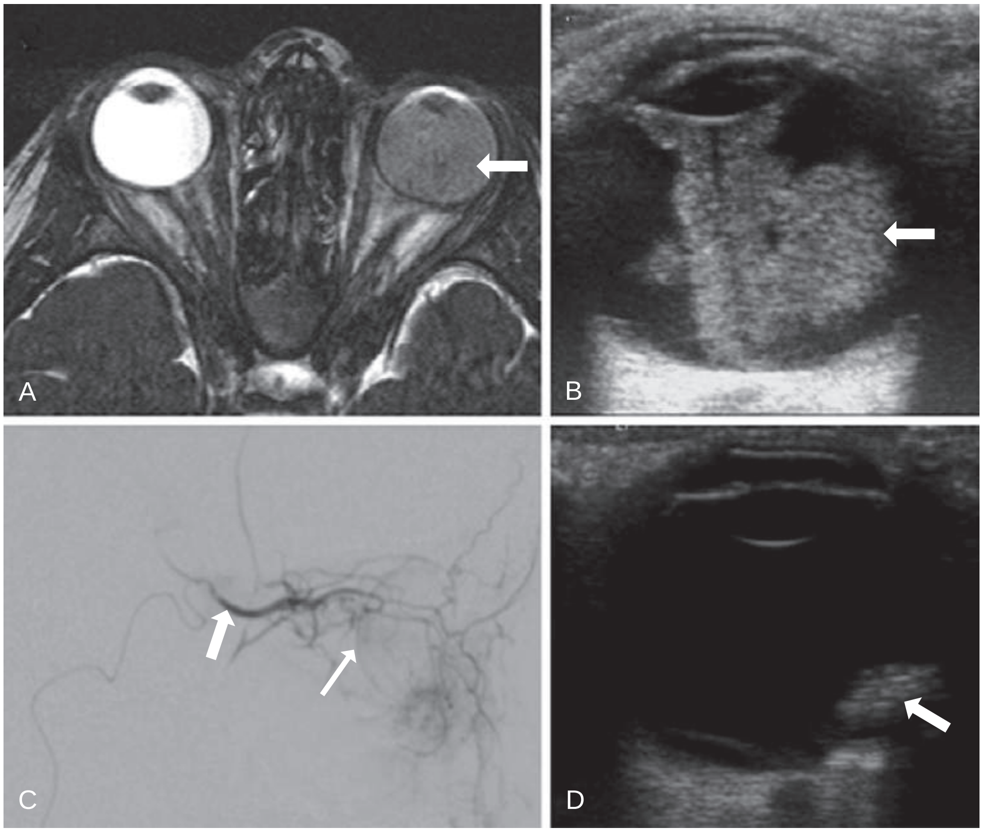

Figure 66-132 Intraarterial chemotherapy. **A**, Axial T2-weighted image of the orbits showing a hypointense retinoblastoma filling the entire left orbital cavity *(arrow)*. **B**, Ultrasound obtained during the first intraarterial chemotherapy demonstrating the hyperechoic intraorbital mass *(arrow)*. **C**, Selective left ophthalmic artery angiogram *(thick arrow)* before superselective chemotherapy demonstrating retinal blush *(thin arrow)*. **D**, Ultrasound obtained during the second intraarterial chemotherapy demonstrating the remarkable tumor shrinkage with a very small residual mass *(arrow)*.

Presurgical TACE for pediatric hepatoblastoma has been shown to decrease tumor volume without causing significant chemotoxicity, allowing for complete tumor removal.[416] In unresectable lung metastases having dual supply from pulmonary and bronchial arteries, TACE has been well tolerated as a palliative procedure.[417] TACE has also been used in osseous tumors[418] and in Wilms tumor, demonstrating prolonged time to tumor progression and increased survival compared with surgery alone.[419] Intraarterial chemotherapy for retinoblastoma has been widely accepted for pediatric tumors (Fig. 66-132).[420]

Radioembolization. In transarterial radioembolization (TARE) radioactive materials are used to embolize hepatocellular carcinomas with a technique similar to TACE. External radiation therapy in patients with diffuse hepatic malignancy does not improve overall survival,[421] in part because of the relatively low radiation tolerance of liver tissue when compared with the doses required for tumoricidal effect.[421,422] TARE is usually chosen for chemoinsensitive tumors or when chemotoxicity limit is reached. The technique also involves selective catheterization of the hepatic artery supplying the tumor and injecting yttrium-90 (^{90}Y) microspheres. This has been shown to have less toxicity, higher response rate with a longer time to disease progression, and a similar survival rate in patients with advanced hepatocellular carcinoma when compared with chemoembolization.[423] Potential complications include locoregional radiation effects, pulmonary irradiation, and gastric perforation. To reduce pulmonary or systemic irradiation a diagnostic study is initially performed by injecting ^{99m}Tc-labeled macroaggregated albumin (MAA) (the same tracer used for routine lung scans), allowing the hepatic-to-pulmonary artery shunt fraction to be estimated before embolization.[424] Preprocedure coil embolization of gastrointestinal collaterals prevents gastrointestinal irradiation.

Bland Embolization. This technique is mostly used palliatively in hypervascular tumors like hemangiomas[425] and angiosarcomas,[426] both to control symptoms and arrest tumor growth. It also used preoperatively to decrease the blood loss at surgical resection[427] or to reduce intractable blood loss in pediatric tumors.[428] It is occasionally used to arrest the growth of neuroblastoma metastases causing life-threatening hepatomegaly. The feeding arteries supplying the tumor are selectively catheterized and embolized with either polyvinyl alcohol (PVA) or Gelfoam particles, cutting off the blood supply to cause tumor shrinkage and necrosis (Fig. 66-133).

Ablation Therapy

Ablation results in local destruction of tumor using chemical or mechanical methods. Prior cross-sectional imaging

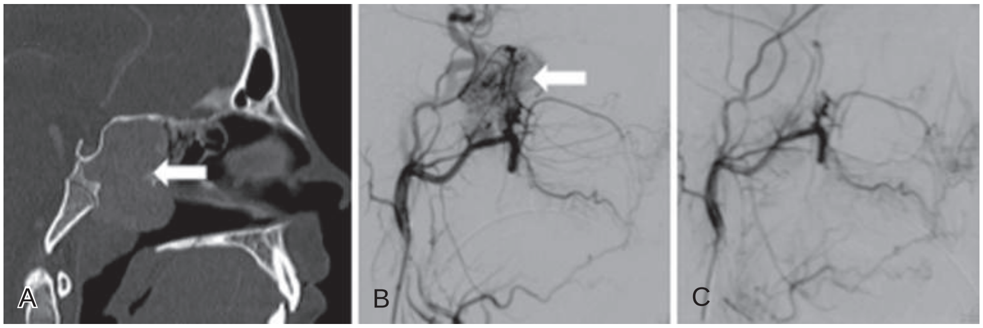

Figure 66-133 Juvenile nasopharyngeal angiofibroma. **A**, Sagittal-CT reconstructed image of the head demonstrates a large nasopharyngeal mass *(arrow)*. **B**, Selective internal maxillary artery injection demonstrating hypervascular nasopharyngeal mass *(arrow)*. **C**, After selective embolization with polyvinyl alcohol particles, there is near complete cessation of flow to the mass with preservation of the normal circulation.

is necessary in most patients to delineate the lesion and its relationship to critical structures like nerves, blood vessels, spinal cord, and hollow viscera, which are prone to injury during local ablation. This also helps plan the tract for probe placements and with assessment of the tumor volume to be treated. Local ablation techniques are most often used to treat hepatic tumors, desmoid tumors, and renal tumors and bony and pulmonary metastases.

Chemical Ablation. This is an established technique for treating hepatocellular carcinoma[429-433] and has been described for treating other solid tumors.[432] It is performed by percutaneously injecting and infiltrating the tumor with alcohol or acetic acid. The cytotoxic mechanism of action of ethanol is through cytoplasmic and membrane dehydration, denaturation of cellular proteins, and small-vessel thrombosis, resulting in coagulative necrosis. Acetic acid causes protein denaturation and dissolution of basement membrane and interstitial collagen, resulting in coagulative necrosis of tumor cells. Although these ablative techniques are technically simple, there is a small risk for nontarget tissue injury, including damage to adjacent blood vessels, nerves, organs, or overlying skin, especially if the tumor lacks a definite capsulation. Recently patients with desmoid tumors have been treated with acetic acid ablation.[434]

Thermal Ablation. These techniques provide cytolysis of the tumor cells either by thermal destruction or ionic agitation.

Radiofrequency Ablation. In this technique small probes are percutaneously directed into the tumor using image guidance like CT or Dyna CT. A radiofrequency generator generates high-frequency (375-500 kHz) alternating current applied directly via these probes, producing ionic agitation and frictional heat, thereby causing coagulation necrosis in tumor target tissue. Because this involves an electric circuit, grounding pads applied to the patient are necessary to allow the exit of the current. Local tissue temperatures reach 60 to 100° C, adequate to produce the cytotoxic effect. Temperatures greater than 100° C are generally not beneficial, because this produces tissue vaporization and carbonization, impeding conductance of the thermal energy and limiting the size of the ablation zone.[435] The burn time varies between 6 and 12 minutes. Proper placement of the grounding pads in full contact with the skin without any air pockets is necessary to avoid burns.[436]

Different tissues conduct electrical currents to different degrees. Blood vessels and bile ducts disproportionately absorb current, creating heat sinks that can confound planned heating of target ablation zones. Strategies to limit the temperature drop include internal cooling of the probe with chilled water, diffusion of water along the electrode tines, or preembolizing the feeding arteries adjacent to the tumor.[435] In children, radiofrequency ablation is most commonly used to treat osteoid osteoma (Fig. 66-134), osteoblastomas, and chondroblastomas.[437] Radiofrequency ablation has been used for large hepatic adenomas,[438] Wilms tumor,[439,440] and desmoplastic round-cell tumors in children.[441] A phase I study to determine the toxicity of radiofrequency ablation for solid tumors in children concluded that toxicity is limited and that radiofrequency ablation may offer a local control alternative in carefully selected pediatric patients.[442]

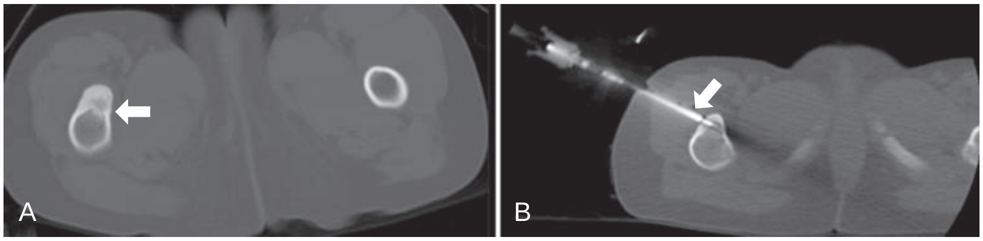

Figure 66-134 Radiofrequency ablation. **A**, Axial CT image of the hips demonstrates a painful sclerotic osteoid osteoma at the anterior cortex of the right femur *(arrow)*. **B**, The tumor was treated with radiofrequency ablation *(arrow)*, resulting in immediate resolution of pain and of the tumor at the follow-up examination.

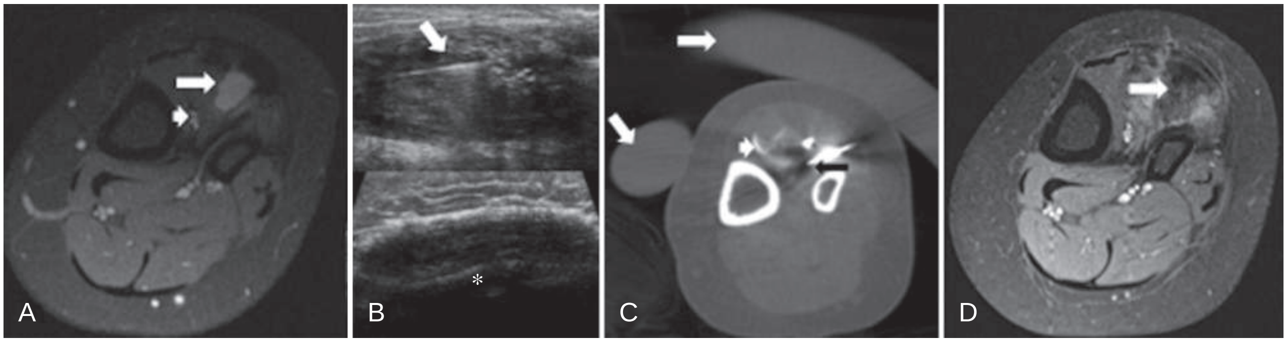

Figure 66-135 Cryoablation. **A**, Axial T1-weighted contrast-enhanced MRI of the left leg demonstrates a well-defined enhancing, recurrent desmoid tumor along the anterior aspect near the peroneus muscles *(arrow)*. Radiofrequency ablation has shown to be effective in pain palliation of painful bony metastases.[443,444]

Cryoablation. This is one of the oldest ablation techniques used and produces tissue destruction by applying nitrogen to surgically exposed tumors.[445] This technique has been surgically used (open or laparoscopic) to treat tumors. With newer imaging techniques that detect small cancers in early stages, together with the availability of smaller cryoprobes, these procedures are now being performed percutaneously using image guidance. The system involves a set of 11- to 17-gauge cryoprobes through which gases from pressurized cylinders are circulated to produce the desired effect of freezing and thawing. Argon gas is used to produce freezing (cooling), and helium gas is used to produce thawing (warming). The Joule-Thompson effect of rapid gas expansion is the basis for rapid cooling of the metallic cryoprobes when there is sudden release of highly pressurized argon gas from the probe. As low as –100° C is reached within a few seconds. On a similar principle, there is production of heat caused by rapid expansion of helium gas that causes local warming. These effects are used alternatingly in a cycle with two 10-minute freezes separated by a 5-minute passive thaw to optimize tumor destruction. There is irreversible tissue destruction that occurs at temperatures below –20 to –30° C. Mechanisms causing cell death are by direct freezing, denaturation of the cellular proteins, cell-membrane rupture, cell dehydration, and ischemic hypoxia.[435] There is formation of an ice ball at the tip of the cryoprobe, the size of which can be either fixed or varied (V-probe), depending on the type of probe used. The size of the ice ball with respect to the tumor volume coverage can be carefully monitored using CT[446] intermittently every 2 to 3 minutes.

Once adequate freezing of the tumor volume is achieved, cryoablation is stopped, thus preventing injury to the adjacent normal structures. Unlike radiofrequency ablation, there is very little or almost no pain after cryoablation. Additionally, larger tumors adjacent to critical structures can be treated more safely. Nerve injury, skin blistering, and bowel injury have been reported with this modality. However, these effects can be minimized by image-based planning, use of temperature monitoring probes to measure adjacent tissue temperatures, careful monitoring of ice-ball formation, and use of tissue protection (Fig. 66-135) including hydro-dissection and warm saline bags over the skin. Cryoablation has been effectively used for treating desmoid tumors,[447] in palliation and local control of Ewing sarcoma,[448] and for painful bony metastases. Percutaneous cementoplasty has also been used as an adjuvant with radiofrequency ablation[449] and cryoablation in palliative pain management.

Microwave Ablation. This system consists of a microwave generator and a set of internally cooled antennas. Most microwave antennas are straight and needlelike with variations such as monopole, dipole, triaxial, choked, or slotted. These antenna shafts are as small as 17 gauge and are cooled by circulating chilled saline or by using compressed carbon-dioxide gas. This allows for delivery of higher powers for longer times to produce larger ablation zones. The generators emit 915 to 2450 MHz microwaves, creating high-speed microwaves that cause rapid vibration and rotation of the molecular dipoles within the ablation zone. This ionic agitation produces frictional heating and thermal coagulation of the tissue. Unlike radiofrequency ablation, the heating energy is deposited directly at the antenna rather than by creating a resistive heating circuit. This precludes the necessity of using grounding pads and chance of having skin burns. Additionally, there is less influence of tissue impedance factors like perfusion-mediated cooling. This system can create rapid heating of tumor tissue to greater than 100° C very quickly.[450] Multiple applicators can be safely placed in one session to optimize the ablation volume.[451,452] The use of microwave ablation has not been routine in children, but it is becoming more popular in adults for ablation of liver, lung,[453] and bone tumors.[454]

Laser Ablation. Although not widely used, laser ablation has also been used for treating tumors. An optical laser fiber transmits infrared light energy into the tumor to produce heat and coagulation necrosis.[435] The 17-gauge fibers are coaxially placed through 14-gauge guide needles, and the active tip is exposed. The size of induced zone of ablation depends on the laser wavelength, thermal and optical properties of the tissue, total duration of energy application, power used, diameter of the fiber, fiber tip, and number of fibers used sequentially or simultaneously for ablation.[455,456] An additional advantage of lasers is their MRI compatibility. Laser ablation has been used in the treatment of osteoid osteomas[457,458] and in lung metastases.[459]

High-Intensity Focused Ultrasound. Ultrasound waves generated by high frequency vibrations of up to 10 MHz are focused into a small discrete target region using a concave or parabolic arrangement.[460] When the local tissue absorbs this acoustic energy there is production of thermal energy, which creates coagulative tissue necrosis. Other changes, including tissue cavitation, microstreaming, and radiation forces generated during this process have been reported to contribute to the overall tumor lysis. Dose delivery to targeted tissues depends on the transducer array, the energy input, and the tissue attenuation that occurs between the transducer and the target.[461] This technique is entirely noninvasive and does not require incisions, general anesthesia, or blood transfusions, making it more appealing than the other modes of ablation. To minimize inadvertent injury to adjacent structures guidance and monitoring of acoustic therapy is critical. Sonography and MRI, especially in the obese,[462] can be used for image guidance and monitoring. Dynamic MRI temperature mapping to assess the ablative zone can also be performed.[463,464] Given the inherent behavior of ultrasound waves, this modality has limitations for lesions that are covered by bone or air-containing viscera, like bowel, which provide very high impedance to these waves. High-intensity focused ultrasound has been used in the treatment of desmoids,[465] bone,[466] and other solid tumors.[467]

Irreversible Electroporation. Irreversible electroporation (IRE) is novel technique in which high-voltage microsecond electrical pulses are applied through percutaneously placed probes into the tumor tissue. This technique causes tumor lysis by creating permanent pores in the cell membrane, which leads to apoptosis.[468] There is no generation of thermal energy; therefore critical structures like blood vessels, biliary ducts, and nerves are not adversely affected.[469,470] No grounding pads are necessary, thus avoiding possible skin burns. Most research on its application has been for pancreatic,[470] liver, pulmonary, and renal tumors.[471]

Supportive Care

Interventional radiologists play a major role in providing supportive care to cancer patients. These patients are usually referred after failed attempts at vascular accesses by other services or as an alternative to high-risk operations. By combining innovative approaches with image guidance and technical skill, these procedures provide a relatively safe and effective option in many difficult clinical situations for managing complex cancer patients.

Venous Access

Venous access in cancer patients is a major requirement for chemotherapy and nutritional support. It can also cause concern in small, underweight children with poor venous caliber. Maintenance of access can be problematic in patients with chronic venous stenosis resulting from long-standing line placement. Central line and peripherally-inserted central catheter (PICC) placements are commonly performed procedures in interventional radiology. These can be tunneled and partially buried underneath the skin at their exit points to provide a secure long-term intravascular access. Chemotherapy port placements can also be performed by interventional radiologists, a procedure ideally coordinated with the patient undergoing image-guided needle biopsy. This is shown to be safe and successful with a low rate of complications.[472,473] The initial vessel access is obtained using direct ultrasound guidance with a single anterior wall puncture, decreasing access time and complication rate and improving overall success of access.[474,475] Catheter position can be manipulated and confirmed simultaneously using fluoroscopy.

For central line placements or chemotherapy port placements, interventional radiologists prefer the internal jugular vein for access over the subclavian vein approach preferred by the surgeons (Fig. 66-136). This choice prevents the “pinch-off syndrome” caused by catheter kinking and is not associated with pneumothorax, hemothorax, and brachial plexus injury seen in the subclavian venous approach.[476] Chronic indwelling subclavian lines can also cause central venous stenosis. This has the disadvantage of precluding placement of dialysis fistulae in the upper extremity and making placement of peripherally inserted intravenous catheters more challenging.[477] Placement of these lines in interventional radiology is more accurate, less traumatic, and greatly reduces chances of inadvertent neurovascular injury. In patients with venous stenosis, venography can also be performed to assess for collateral patency and placement of venous lines using these pathways (Fig. 66-137). Paravertebral veins, internal thoracic veins, external jugular veins, although tenuous, can be safely accessed using sonographic guidance for placement of venous access in patients with inaccessible extremity veins.[478] Salvage procedures such as repositioning and removal of incorrectly positioned catheters (Fig. 66-138), fibrin stripping of occluded central venous catheters, and stenting of stenosed SVCs can also performed conveniently in interventional radiology.[476]

Ancillary Supportive Care

Interventional radiology also offers other supportive care in oncology patients, especially in palliative care. Enteric access for providing nutritional requirements becomes essential in cancer patients who feed poorly for a variety of reasons. Primary gastrostomy and transgastric jejunostomy tubes can be primarily placed with percutaneous nonendoscopic techniques using fluoroscopic guidance[479] and have the advantage of avoiding inadvertent bowel injury.[480] The transgastric tube may be inserted during the initial placement, avoiding the need for another tube

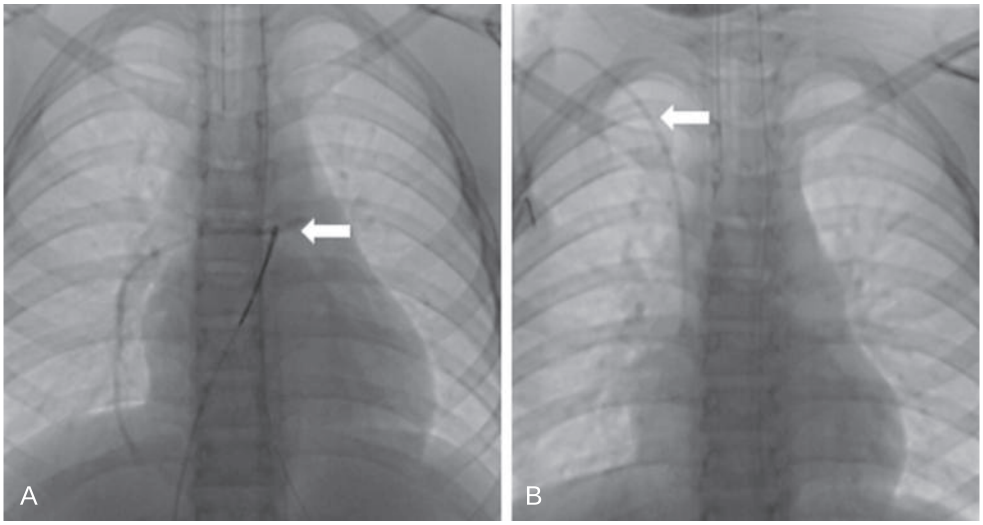

Figure 66-136 Port placement. **A,** Frontal chest radiograph demonstrates the migrated catheter of a chemotherapy port placed via the left subclavian vein. The proximal end of the catheter was floating in the main pulmonary artery with the distal end trapped in the lower branch of the right pulmonary artery. This was snared in the main pulmonary artery *(arrow)* and removed. **B,** A new chemotherapy port was then placed using a right internal jugular venous approach *(arrow)*.

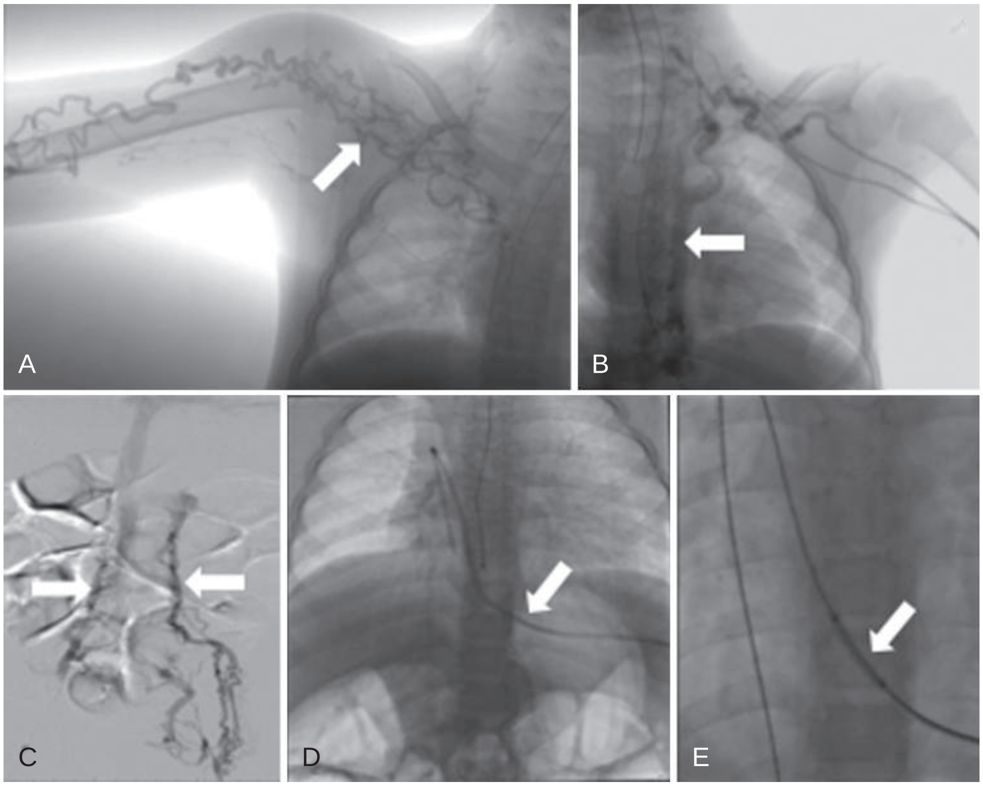

Figure 66-137 Difficult venous access. **A-C,** A patient with an imminent requirement for a central line had bilateral upper and lower extremity venograms demonstrating thrombosis of normal veins with extensive collateralization *(arrows)* diverting flow to the cava. **D,** Because of poor venous access, a posterior paravertebral vein was accessed, and a central line was inserted via the hemiazygos vein *(arrow)*. **E,** One year later there was line damage requiring an exchange. During the exchange there was extreme resistance at the access site with stenosis of the hemiazygos vein, which was angioplastied *(arrow)* to achieve successful exchange.

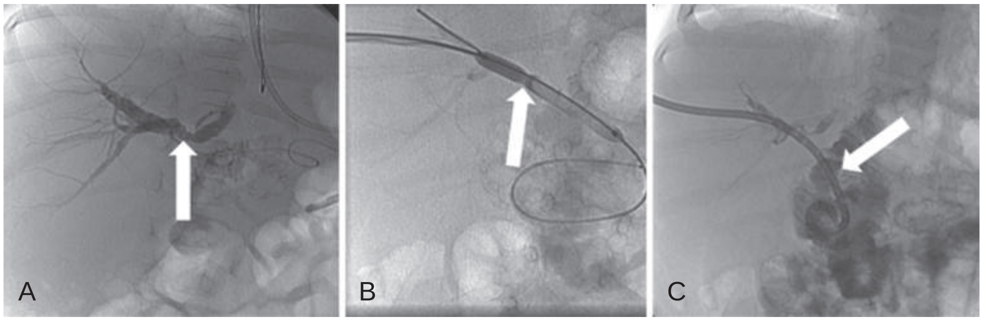

Figure 66-138 Hepatobiliary intervention. **A**, Percutaneous transhepatic cholangiogram in a liver transplant patient with elevated liver enzymes showing biliary strictures *(arrow)*. **B** and **C**, The stricture at the confluence was dilated (*arrow* in **B**) and a biliary drain to the jejunum (*arrow* in **C**) was placed, relieving the patient's symptoms.

conversion, as is required for endoscopically placed tubes. The routine exchange of these tubes is performed in interventional radiology, providing a dedicated and consistent team for support in the maintenance of these tubes.

Certain complex procedures, including biliary interventions such as percutaneous cholangiograms (PTCs), percutaneous transhepatic biliary drain (PTBD) placements (see Fig. 66-138), percutaneous transhepatic intrabiliary biopsies, and cholecystostomies are occasionally performed in pediatric oncology patients but are more commonly encountered in adults. Interventional radiology procedures like PTBD placement and hepatic vein dilation are most often used after liver transplant in cancer patients. These include percutaneous and transjugular liver biopsies performed with ultrasonographic and fluoroscopic guidance for the diagnosis of graft disease; angioplasty and stent placement for treatment of vascular and biliary occlusion, stenosis, and stricture; and catheter placement for drainage of fluid collections.[481,482] In patients with portal hypertension a transjugular intrahepatic portosystemic shunt can be placed to decompress the liver as a bridge to transplantation.[483] In the genitourinary system, percutaneous nephrostomy catheter placements, nephroureteral catheters, ureteral stents, and suprapubic catheter placements for extrinsic abdominal or pelvic tumors causing urinary obstruction are all performed in interventional radiology (Fig. 66-139).[484]

Occasionally catheter-directed thrombolysis of the deep vein thrombosis in cancer patients[485] and placement of IVC filters to prevent pulmonary embolism are other supportive procedures performed by interventional radiologists. Patients with multivisceral transplants, including bowel transplant, may suffer recurrent chylous fluid accumulation. Intranodal lymphangiogram performed by accessing a groin node is a novel procedure that helps diagnose this condition and allows percutaneous embolization (Fig. 66-140) to treat this challenging posttreatment complication.

NEW IMAGING TECHNIQUES

Molecular Imaging

Historically the standard tools of radiology—CT, MRI, and ultrasound—have provided primarily anatomic information, with relatively little direct functional information being evident. Nuclear medicine imaging has

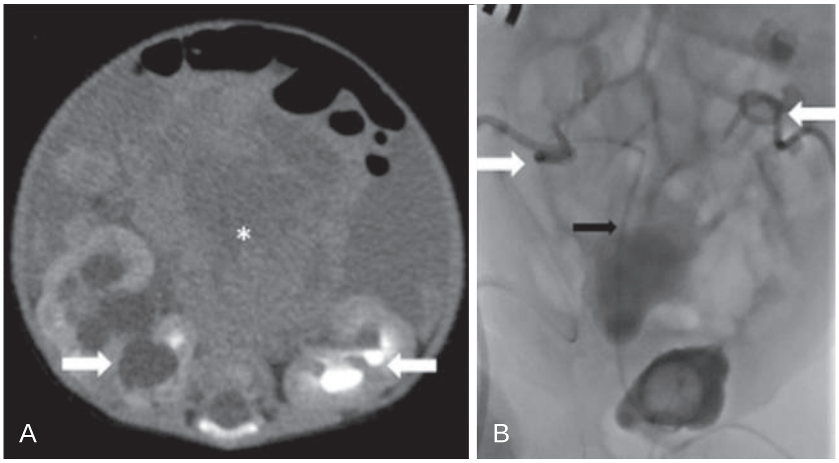

Figure 66-139 Genitourinary intervention. **A**, Axial CT image of the abdomen demonstrates a large rhabdoid tumor compressing the ureters and causing bilateral hydronephrosis. **B**, Bilateral percutaneous nephrostomy catheters *(white arrows)* and a right ureteric stent *(black arrow)* were placed to provide urinary diversion.

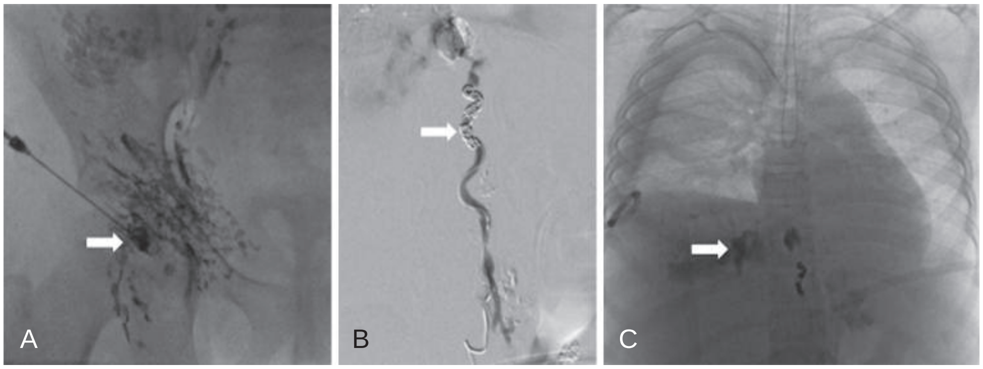

Figure 66-140 Intranodal lymphangiography and embolization. **A**, A child with recurrent chylous effusion after multivisceral transplant underwent intranodal lymphangiography *(arrow)*. **B**, The cisternae chyli was percutaneously embolized with coils and glue *(arrow)*. **C**, The persistent leak *(arrow)* that was causing recurrent pleural effusions stopped.

provided useful functional information but has been limited by the lack of accompanying anatomic detail available with conventional planar and SPECT techniques, although PET imaging has provided a considerable improvement in the anatomic resolution, particularly with the use of hybrid imaging approaches. Of the three major cross-sectional imaging technologies, MRI has come closest to providing direct information about cellular function, for example by employing diffusion-weighted imaging to assess regions of localized ischemia and using hydrogen (^{1}H) spectroscopy to derive metabolic information about specific regions being imaged. Functional MRI of the brain relies on relative changes in blood oxygen level in metabolically active tissues to yield exquisite information about cerebral activation in response to various stimuli. The relative success enjoyed by MRI in generating functional images derives mostly from the rich and varied information contained in the MR signal from different materials. Although most of the MR information being imaged routinely arises from the protons contained in hydrogen atoms from water molecules and lipids, a vast amount of metabolic information can also be derived from MR signals arising from molecules other than water.

The U.S. Food and Drug Administration (FDA), in its critical-path initiative, has emphasized the need to increase the speed, efficiency, and cost-effectiveness of drug development for cancer and other diseases.[486] Molecular imaging and functional imaging probes have great potential to identify and characterize disease-specific targets and to provide target- and treatment-specific imaging end points for therapy. In particular, as markers of biological response, imaging end points that characterize cellular vitality or apoptosis, receptor down-regulation, or functional inactivation, and treatment-specific changes to cellular metabolism will be critical in determining the success or failure of newer classes of molecular-based therapies. As has been learned with imatinib and gastrointestinal stromal tumors, noncytolytic therapies that slowly extinguish tumor metabolic activity do not immediately result in tumor shrinkage, and imaging techniques that directly measure tumor metabolism are necessary to directly reflect the response to therapy.[487] In addition, for many molecularly targeted agents such as antibodies or receptor-targeted agents, it is unclear whether the agents ever localize in tumor in vivo. For these compounds, it is critical to develop surrogate end points of response. The ability to directly image the distribution and targeting of such agents in vivo would significantly benefit this assessment, particularly when there is a poor overall clinical response to therapy. Phase 1 trials of therapeutic agents in particular offer an opportunity to use imaging as means of establishing drug activity at a time when therapeutic efficacy may not be the primary or anticipated goal of therapy. As shown in Figure 66-141, in a phase I/II study of the insulinlike growth factor 1 receptor (IGF1R)–targeted agent cixutumumab[488] after just one 4-week cycle of therapy a child with metastatic fibrosarcoma showed a nearly complete metabolic response to therapy despite minimal change in tumor size. Conventional measures of response would have concluded there was no activity in this patient, highlighting the importance of molecular imaging techniques in assessing novel noncytolytic approaches to therapy.

Newer functional imaging approaches are also expected to impact treatment strategy and drug design with an emphasis on response-based treatment regimens. This allows patients with a high likelihood of response to be treated less aggressively, whereas those not responding to therapy are identified early and redirected into more aggressive therapeutic regimens.

Molecular imaging has been defined by the Commission on Molecular Imaging of the American College of Radiology as the “spatially localized and temporarily resolved sensing of molecular and other processes in vivo”.[489] Although molecular imaging techniques, particularly in nuclear medicine, have been in use for many years, this terminology has recently been applied to the rapidly growing area of radiologic investigation aimed at developing tools to allow direct imaging of cellular and molecular events. Increasingly there has been recognition that the ability to perform multiparametric functional imaging is likely to provide the greatest insight into tumor or tissue biology and response to therapy by providing quantitative parameters (biomarkers) that derive from

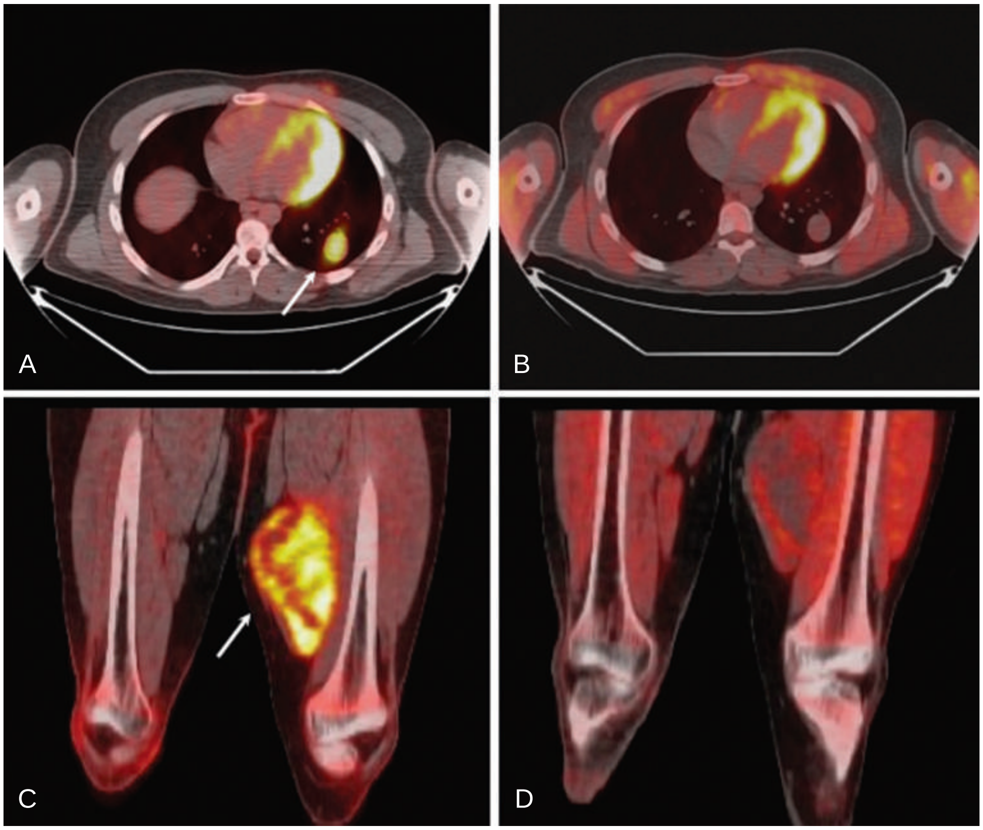

Figure 66-141 Reduction in FDG-PET activity with cixutumumab. Fused axial PET/CT of chest (**A** and **B**) and lower extremities (**C** and **D**) show increased uptake at baseline in metastatic left lower lobe lung nodule (**A**, *arrow*) and intense baseline uptake in a primary left midthigh mass at baseline (**C**, *arrow*) in a patient with metastatic fibrosarcoma. After 2 weeks of cixutumumab therapy, although the lung nodule had not changed in size, there was no significant residual FDG uptake remaining (**B**). Similarly, there was significant reduction in FDG uptake at the primary left thigh site with no apparent change in size of tumor (**D**) after 2 weeks of therapy. *(From Malempati, Weigel B, Ingle AM, et al: Phase I/II trial and pharmacokinetic study of cixutumumab in pediatric patients with refractory solid tumors and Ewing sarcoma: a report from the Children's Oncology Group.* J Clin Oncol *30:256–262, 2012.)*

merging the information obtained from different imaging techniques,[490] for example diffusion- and perfusion-weighted MRI results coupled with metabolic changes visible by PET imaging.[47]

Most of these investigations are still in the early stages of development[486,489,491,492] and include development of optical imaging probes, imaging gene expression, imaging marker genes, tracking cells in vivo, and developing targeted biomolecular conjugates to allow visualization of specific cellular and molecular events in vivo.[493,494] Perhaps the most fruitful area of research has been in the application of near-infrared fluorescent imaging to evaluation of malignant disease.[495-498] Fluorescence in the near-infrared range of the spectrum has been pursued, because these wavelengths penetrate biologic tissue further than visible or infrared light. Light in the visible spectrum is largely absorbed by abundant biomolecules such as hemoglobin that are present in most tissues, whereas light in the infrared range is almost completely absorbed by water.[499] The ability to image fluorescing tissues has long been in use in the laboratory setting but has not yet found clinical utility. The development of "smart" near-infrared fluorescent imaging probes has allowed tumor-specific enzymatic activity to be directly imaged by fluorescence. These probes are synthesized such that the near-infrared fluorophores are attached to a peptide scaffold that, by virtue of its amino acid sequence, can be selectively cleaved by tumor-specific proteases. Fluorescence of the near-infrared fluorophores is quenched because of their close proximity in the intact peptide scaffold. Upon enzymatic cleavage in the tumor, the fluorophores are released, and the resultant near-infrared fluorescent signal provides a specific signal, allowing tumor visualization. This technique has been used successfully to detect tumor-specific cathepsin activity in colon- and breast-cancer models[496] and more recently has been used for real-time hepatobiliary interventions.[493,500] Although the depth of penetration of near-infrared light still limits this technique to structures near the surface, near-infrared fluorescent imaging has been used with success intraoperatively for sentinel lymph node[501] identification and has great potential to provide guidance in determining tumor margins and sites of lymph node spread and in evaluating cavities and tissue linings such as the peritoneum, which are poorly imaged by other techniques.[502]

Magnetic Resonance Spectroscopy

Whole body MRI imaging uses the aggregate signal characteristics of a given tissue to generate high-resolution images that reveal information about both the anatomy and state of health of the tissue but give little direct information about the biochemical makeup of the tissue. In contrast, MR spectroscopy focuses on acquiring chemical information from small volumes of tissue, with the aim of characterizing the ongoing chemical processes that are unique to specific tissues. This is accomplished by separating the signal derived from specific tissue and cellular constituents into their different chemical forms. The protons contained within tissues experience a molecular environment that is unique to the tissue. These variations in molecular environment produce alterations or chemical shifts in the resonant frequency of the constituent protons. In theory, when the nuclear MR (NMR) signal is displayed as a function of resonant frequency, the different chemical forms in the tissue should yield a unique "spectroscopic fingerprint." In practice, large water and lipid peaks dominate the proton NMR spectra from biological tissues, with the less abundant elements giving lower signal. Because of the need to reduce heterogeneity of tissue within the voxel being interrogated, the small volumes of tissue evaluated by MR spectroscopy generally produce low signal, and prolonged imaging times are needed to acquire useful spectra. With prolonged imaging times, degradation of spectra from motion artifact occurs, and to date the majority of the routine spectroscopic examinations have focused on applications in the brain, where the tissues being examined remain relatively static.[52]

With higher field-strength magnets, faster scanning sequences, and advances in postprocessing techniques, ^{1}H-MR spectroscopy is increasingly being used for nonneurologic body applications. Some investigators have used ^{1}H-MR spectroscopy together with dynamic contrast-enhanced MRI to show that increases in vertebral marrow-fat content and accompanying decreases in marrow perfusion correlated with varying states of osteopenia and osteoporosis.[503] Others have evaluated the utility of ^{1}H-MR spectroscopy to characterize and monitor response to therapy in some pediatric solid tumors including neuroblastomas[504] and in adult prostate cancer.[505] Response of neuroblastoma to chemotherapy has been shown to correlate with decreases in cellular Cho peaks,[506] although this had not been validated against conventional imaging techniques in prospective clinical trials.

^{1}H-MR spectroscopy has also been used to characterize bone and soft-tissue tumors, with elevated Cho levels detected in lesions shown to have a malignant histology but not in the majority of benign lesions.[507] Quantitative spectroscopic measurement of trimethylamine concentration in MPNSTs has also been reported as having potential for the differentiation of benign and malignant lesions[508] and could be combined with FDG uptake for better characterization of these lesions. Several years ago, Preul et al. suggested that a pattern-recognition analysis of the biochemical information obtained from ^{1}H-MR spectroscopy of brain tumors could reliably distinguish benign, low grade, and high-grade tumors and suggested that specific tumor and nontumor "fingerprints" might ultimately provide an accurate noninvasive preoperative characterization of particular lesions.[509] Although considerable progress has been made, much work is still needed to develop a similar "library" of characteristic spectra for other pediatric solid tumors.

Other nuclei that can be evaluated with MR scanners, particularly at higher field strengths, include ^{31}P-phosphorus, ^{13}C-carbon, and ^{23}Na-sodium. These nuclei all have lower gyromagnetic ratios than protons and resonate at lower frequencies than protons for a given field strength. The molecules and ions containing these nuclei are also much less abundant than water protons, so that the signal-to-noise ratios from these nuclei are low compared with those associated with proton MRI. As such, large voxels must be sampled from a given tissue in order to obtain a sufficient signal-to-noise ratio with a reasonable scan time. ^{31}P-MR spectroscopy enables the observation of energy metabolism and intracellular compartmentation through the signals of phosphomonoesters (PMEs), phosphodiesters (PDEs), inorganic phosphate (P_is), and nucleotide triphosphates, mainly adenosine triphosphate (ATP). Depending on the tissue being studied, a peak from phosphocreatine may also be seen (such as brain and muscle). When compared to ^{1}H-MR spectroscopy in the evaluation of bone and soft-tissue tumors, ^{31}P-MR spectroscopy was superior in identifying lesions shown to have a malignant histology.[507] Whether ^{31}P spectroscopic measurement of intratumoral changes in a phosphate metabolite profile will be feasible and valuable in response assessment remains to be validated.

SURVEILLANCE IMAGING

Surveillance imaging in pediatric oncology presents a unique challenge. Since the mid 1960s new treatment developments have continued to result in dramatic improvements in event-free and long-term overall survival rates for patients with many pediatric cancers.[510] For example, in Hodgkin lymphoma, long-term survival rates of greater than 90% can now be expected, with even higher rates of survival in lower-stage disease.[137,511] Along with these improvements in overall survival there has been a shift in the treatment paradigm. With efforts to develop criteria for upfront risk stratification coupled with response-based reduction in treatment intensity, current approaches are aimed at reducing late effects and improving overall treatment-related complications while preserving excellent long-term treatment outcome and survival. At the same time, advances in diagnostic imaging have led to a corresponding increase in number of imaging evaluations performed on these same patients.[512] Increases in use of conventional radiography, CT, MRI, and PET imaging, although providing important information about disease stage and response to therapy, are also costly and contribute to cumulative exposure to ionizing radiation, particularly from CT and nuclear medicine examinations.[512,513] Even though the doses of radiation from diagnostic imaging examinations are relatively low (particularly when compared with therapeutic doses) they are not without potential risk. With the improvements in patient outcome, a number of studies have begun to question the need for repeated high-intensity surveillance imaging and additional exposure to potentially harmful ionizing radiation for a population of patients who do very well once they have successfully completed therapy.[514-516] Patients with Hodgkin lymphoma often receive a large number of off-therapy imaging studies with no effect on overall patient outcome.[514] Similarly CT protocols that routinely include the pelvis in off-treatment surveillance of patients with Wilms tumor had no effect on disease detection and exposed gonadal tissue to potentially harmful additional radiation.[517] A recent study of patients with low-stage gonadal germ-cell tumors showed that tumor markers provided a sensitive and specific means of detecting patients with disease relapse; no relapses were identified in patients who were marker-negative.[518]

Taken together these studies underscore the need to reassess the frequency and type of surveillance imaging needed for the routine off-therapy monitoring of patients who have had successful treatment of their disease. Practitioners must be cognizant of the need to provide reassurance that disease relapse, if present, will be detected as early as possible while at the same time balancing these assurances against performing unnecessary, costly, and potentially harmful studies that have no impact on outcome.[519]

CONCLUSION

The approach to imaging pediatric oncology patients is rapidly evolving. The era when the radiologist played a peripheral role in the care of the child with cancer has been left behind. As outlined in this chapter, the imaging of children with cancer is complex and the role of radiology has changed. The development of new diagnostic imaging techniques and image-guided therapeutic interventions has lead to a new paradigm in which treatment designs are increasingly relying on imaging endpoints, with exciting opportunities and challenges to better detect, stage, and monitor malignant disease. The next decade of imaging will require close collaboration between the pediatric oncologist and the pediatric imaging specialist in order to determine which of these imaging techniques are best suited to these patients.

CHAPTER 67

Infectious Disease in the Pediatric Cancer Patient

Lillian Sung, Brian T. Fisher, and **Andrew Y. Koh**

CHAPTER OUTLINE

INTRODUCTION
GENERAL ISSUES RELEVANT TO INFECTIONS
Risk Factors for Infection
Infection Classification
Intervention Approaches
MAJOR PATHOGENS
Bacteria
Fungi
Viral Infections
Protozoal Infections
FEVER AND NEUTROPENIA
Initial Risk Stratification
Initial Investigations
Initial Antibiotic Therapy
Considerations for Low-Risk Patients with Fever and Neutropenia
Modification of Empiric Antibacterial Therapy
Evaluation for Invasive Fungal Infection and Empiric Antifungal Therapy
PROPHYLACTIC STRATEGIES
Antibacterial Prophylaxis
Antifungal Prophylaxis
Granulocyte and Granulocyte-Macrophage Colony-Stimulating Factors
Prevention of Central Line–Associated Bloodstream Infection
INFECTIOUS ISSUES IN PEDIATRIC CANCER PATIENTS IN LOW- AND MIDDLE-INCOME COUNTRIES
RECENT DIRECTIONS INVOLVING PRECLINICAL RESEARCH

INTRODUCTION

Infections are important issues faced by children with cancer. Invasive bacterial and fungal infections are problematic mainly in those receiving intensive treatment. Viruses may also be life-threatening in specific circumstances. Furthermore, non–life-threatening infections such as upper respiratory tract infection may still affect treatment and quality of life, particularly if febrile illnesses occur during neutropenia. In an effort to provide a comprehensive discussion of infection in pediatric cancer patients, this chapter focuses on general issues such as risk factors for infection, infection classification, and then approaches to intervention. Next, the chapter reviews major opportunistic pathogens, the risk factors and epidemiology of fever and neutropenia (FN), the therapeutic options for prophylaxis, infectious issues in pediatric cancer that are specific to low- and middle-income countries (LMIC), and recent directions involving preclinical research.

GENERAL ISSUES RELEVANT TO INFECTIONS

Risk Factors for Infection

Children with cancer are predisposed to infection for several reasons. The most common and important risk factor is neutropenia caused by myelosuppressive chemotherapy and cancer itself. Greater depth and duration of neutropenia are directly related to the risk of invasive bacterial and fungal infection and infectious mortality.[1,2] Corticosteroids are commonly used as anticancer therapy and as supportive care. The negative consequences of corticosteroids on the host immune system predispose to infections such as *Pneumocystis jiroveci,* other fungi, and bacteria and may be an independent risk factor for sepsis and infectious mortality.[3] Intensive chemotherapy also predisposes to infection through disruption of important protective anatomic barriers. The development of mucositis after chemotherapy administration provides a portal of entry for organisms colonizing the oral cavity and is a particularly important risk factor for viridans group streptococcal bacteremia.[4,5] Likewise, compromise of the gastrointestinal mucosa may clinically manifest as enteritis, typhlitis, and colitis and can facilitate translocation of enteric pathogens to the bloodstream. Beyond chemotherapy and corticosteroids, certain procedures performed in this patient population may predispose to infection. In many countries central venous lines (CVLs) are routinely used in patients with cancer, resulting in a risk for catheter-related bloodstream and local CVL site infections. Additionally, many children require surgery for various reasons, including tumor resection, and such procedures predispose to surgical site infection. Finally, children who receive allogeneic hematopoietic stem cell transplantation (HSCT) have a unique predisposition to infections related to graft-versus-host disease (GVHD) and therapies used to prevent and treat this complication of transplantation.[6]

Infection Classification

Infections can be classified by etiology as bacterial, fungal, viral, or protozoal, and these pathogens may infect sterile or nonsterile sites. The overall risk of infection varies depending on many factors, with intensity of chemotherapy being very important. Children who receive the most intensive chemotherapy include those with acute myeloid leukemia (AML). One study demonstrated that more than 60% of children with AML have at least one microbiologically documented infection during each phase of therapy, and the cumulative risk of infection-related mortality was 11 ± 2%.[7] In a subsequent pediatric AML analysis, more than 80% of children experienced at least one sterile site bacterial infection and 14% experienced at least one sterile site fungal infection throughout chemotherapy. The risk of sterile site bacterial infection was 30% to 60% per chemotherapy course.[8] In contrast, some children who receive non-myelosuppressive therapy such as those receiving maintenance therapy for acute lymphoblastic leukemia (ALL), have a very low risk of sterile site bacterial or fungal infections.[9]

Infections may also be classified by type of infection: microbiologically documented, clinically documented, or fever of unknown origin (FUO). In an analysis of children with cancer or recipients of HSCT presenting with FN, 80% of episodes were ultimately classified as FUO, 13% had a microbiologically confirmed etiology, 6% were clinically documented infection, and 2% were invasive mycosis.[9] The distribution of the etiology of FN will change depending on the presence of the aforementioned risk factors, especially the intensity of chemotherapy administered.

Intervention Approaches

The major approaches to reduction of infectious morbidity and mortality are prophylactic, empiric, and definitive treatment approaches. With prophylaxis, antimicrobials are administered before onset of fever or other clinical signs of infection. Empiric therapy consists of the administration of antimicrobial agents with early signs of infection, such as fever. Definitive treatment consists of administering specific antimicrobials once an infection has been documented.

MAJOR PATHOGENS

Bacteria

Bacteria are the most common cause of invasive infection in pediatric cancer patients. Over the last three decades, there has been a shift from gram-negative organisms being responsible for most infections in patients with cancer to gram-positive infections predominating.[10] The shift toward gram-positive agents has been attributed to the wide-spread use of CVLs, chemotherapy regimens associated with mucositis, and routine use of antibiotics with gram-negative activity.[11] The most common gram-positive infections are coagulase-negative staphylococci, viridans group streptococci, enterococci, and *Staphylococcus aureus*. The major types of gram-negative infections are *Escherichia coli, Klebsiella* species, and *Pseudomonas aeruginosa*.[9] Bacterial sterile site pathogens are most commonly tested for and isolated from blood culture, followed by urine and, less frequently, cerebrospinal fluid.

Fungi

Pediatric patients requiring intensive chemotherapy treatment for cancers such as AML, relapsed ALL, and allogeneic HSCT have the highest risk for invasive fungal infection (IFI) because of the resultant depth and duration of neutropenia. Additional IFI risk factors include mucositis, corticosteroid use, and antibiotic exposure.[12-20] The most common fungal infections in pediatric cancer are *Candida* spp. and *Aspergillus* spp.[21] Sterile site candidal infections typically occur in the blood and urine. In contrast, invasive aspergillosis typically involves the lungs, sinuses, gastrointestinal tract, and brain. Emerging fungal pathogens that are increasingly being encountered in pediatric oncology are Mucorales (formerly referred to as zygomycetes) and *Scedosporium* spp. These are particularly concerning because they tend to be fatal and are challenging to diagnose antemortem.[22,23]

P. jirovecii is a yeastlike fungal species that classically causes pneumonia in children with acute leukemia who do not receive *P. jirovecii* pneumonia (PCP) prophylaxis. In addition to chemotherapy exposure, corticosteroid use and age younger than 2 years are also risk factors for PCP.[24,25] PCP prophylaxis is considered standard care for many pediatric malignancies, including acute leukemia and HSCT recipients. Trimethoprim-sulfamethoxazole (TMP-SMX) is the prophylactic drug of choice. Although the optimal dosing regimen is not clear, administration regimens of 2 or 3 days per week are most common and have been shown to be reasonably effective.[26,27] Alternative regimens for allergy or other toxicities include oral dapsone, oral atovaquone, and inhaled pentamidine. Intravenous pentamidine is often used in children younger than 5 years who cannot tolerate the other options. However, clinicians should be aware that the effectiveness of intravenous pentamidine is questionable.[25]

Viral Infections

There are many viruses that can result in infections in pediatric cancer patients.[28] The list of potential agents continues to evolve with improved diagnostic abilities for previously unrecognized pathogens such as human metapneumovirus (HMPV). In one pediatric cancer series, respiratory syncytial virus (RSV) (31%) and rhinovirus (23%) were the most frequently detected respiratory viruses, followed by parainfluenza (12%) and influenza A (11%).[29] RSV usually does not cause life-threatening infections in children with cancer. However, in patients with AML and HSCT recipients who do acquire RSV, infection may progress to lower respiratory tract involvement. In this setting RSV infection is associated with a 14% case fatality rate in patients with AML and a 50% case fatality rate in pediatric HSCT recipients.[7,30] Adenovirus may also cause serious infection, particularly in HSCT recipients,[31] and is a frequent cause of death in this setting.[32-35] Other viral infections, including varicella-zoster virus (VZV), influenza, and cytomegalovirus, are typically not life threatening in pediatric patients with cancer who are receiving less intense therapy, but they may cause severe infection and infectious mortality in the most intensively treated children. Conversely, some infections, such as severe acute respiratory syndrome (SARS), can cause fatal infection in immunocompetent patients but is rarely associated with severe illness in pediatric cancer.[36] It is hypothesized that an intact immune system is responsible for severity of illness and fatality in SARS, thus explaining this apparent paradox.

Protozoal Infections

In general, protozoal infections are not a common cause of fever in children with cancer in high-income countries, although these pathogens may be more prominent in some LMICs.[37]

FEVER AND NEUTROPENIA

FN is one of the most common complications of cancer therapy in pediatric patients. Episodes of FN are associated with considerable morbidity, reduction in quality of life (QoL), and high costs, and fatal outcomes still occur despite aggressive antimicrobial interventions.[2,38] Much research has been conducted in both adult and pediatric FN over the last several decades, which has allowed different therapeutic approaches to evolve while reducing mortality and improving other clinical endpoints.[39,40]

Initial Risk Stratification

Children with FN are not a homogenous group. Determining which children are at lower risk of complications can allow for a reduction in the intensity of therapy and monitoring. Conversely, identifying children at higher risk of complications can allow for escalation of therapy and closer observation.

In adults with FN, the risk stratification schema from the Multinational Association of Supportive Care in Cancer (MASCC) has been validated and is widely accepted as a standard approach. However, the MASCC score cannot be applied to children because age below 60 years and absence of chronic obstructive pulmonary disease are two items in the score and these are not applicable to pediatric patients.[41] At least 25 studies of risk prediction have been conducted in pediatric cancer.[42] These studies have been highly variable using different pediatric cancer populations and different endpoints (e.g., bacteremia, "serious infection," death, and intensive care unit admission), making the results more difficult to interpret.

Although six of these low-risk stratification schemas have been validated in children (Table 67-1), identification of a single schema to be applied across all clinical scenarios has not been feasible, likely because of the divergence in clinical settings. Therefore clinicians should review the six validated low-risk stratification schemas, choose which schema matches their clinical setting, and determine whether the application of that schema is feasible for their center. For example, some rules use biomarkers such as C-reactive protein and would require expeditious analysis and return of results to be useful. Others require clinical judgment and thus require trained health care professionals to be readily available. There are no validated risk stratification schemas to identify the pediatric high-risk patient with FN.

Initial Investigations

At initial presentation, an evaluation for the cause of fever should be conducted. The evaluation begins with a careful history and physical examination, with the assessment focusing on potential sites of infection. Sites that merit particular attention are the mouth to search for herpes simplex virus stomatitis and dental abscess, the exit site and tunnel of CVLs, perianal region for cellulitis and perirectal abscess, and fingers and toes for paronychia.

The standard evaluation should include blood cultures, with further diagnostic testing dictated by clinical signs and symptoms. Blood cultures should be obtained from each lumen of the CVL if present. The utility of a peripheral blood culture at the initial evaluation of FN is controversial. There are seven studies that evaluated the contribution of peripheral blood cultures in addition to CVL cultures in adults and children with cancer or undergoing HSCT.[43-49] When these results were combined, 13% (95% confidence interval [CI] 8% to 18%) of all true bacteremias were identified only by the peripheral blood culture. This result is likely explained by false-negative CVL blood cultures when obtained culture volumes are small.[50] However, it is not known how failure to identify these episodes of bacteremia affect patient outcomes or whether this problem can be overcome by optimizing CVL blood culture volumes. Consequently, the role of peripheral blood culture remains uncertain.

Urinalysis and urine culture testing for the detection of urinary tract infections (UTIs) is also considered controversial in the setting of FN. In immunocompetent children, a UTI is often diagnosed when there is both evidence of pyuria on urinalysis and a positive culture. The state of neutropenia limits the ability to use pyuria as a diagnostic criterion,[51] and reliance on nitrite testing is not ideal because the test may be negative in younger children with UTI.[52] Therefore urinalysis testing has limited utility in the setting of FN. It may be reasonable to obtain a sterile urine culture and define the presence of a UTI on the culture results alone. However, sterile urine

ALL, Acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *CRP,* C-reactive protein; *CXR,* chest radiograph; *FN,* fever and neutropenia; *URTI,* upper respiratory tract infection; *USA,* United States of America.

*"Valid" refers to clinically adequate discrimination of a group at low risk of complications.

collection can be difficult in young children and infants and often requires urinary catheterization, a procedure that is seldom recommended for a neutropenic patient. Therefore where a clean-catch or midstream urine can be collected, the results of urinalysis and urine culture should be included in the initial FN investigations. It is important to remember that antibiotic administration should not be delayed to obtain a urine sample.

There are have been four studies,[53-56] including 540 episodes of FN, that investigated the impact of chest radiography (CXR) as a component of the initial FN evaluation. These studies indicate that pneumonia is detected in fewer than 5% of children without respiratory symptoms and that the omission of routine CXR does not lead to adverse outcomes.[53,57] Thus routine CXR should not be performed in asymptomatic children with FN.

Initial Antibiotic Therapy

In general, empiric antimicrobial therapy choices should provide good coverage for gram-negative organisms with some gram-positive coverage. In particular, for high-risk patients with FN, antibiotic therapy should include coverage for viridans group streptococci and *P. aeruginosa*. Various factors must be considered when determining an empiric antibiotic regimen, route of administration, and location of therapy. These factors include patient and family social factors, clinical presentation, ability of the hospital to support an ambulatory approach, availability and cost of drugs, and local hospital resistance patterns.

The role of combination antibiotic therapy versus monotherapy for FN has been debated. Monotherapy was supported by two metaanalyses that compared monotherapy versus an aminoglycoside-containing regimen in FN[58] and in immunocompromised patients with sepsis.[59] These analyses demonstrated that monotherapy is not inferior and is less toxic than combination therapy. The meta-analysis in FN observed fewer treatment failures with monotherapy (odds ratio [OR] 0.88, 95% CI 0.78 to 0.99) but included only four trials that enrolled patients younger than 14 years of age.[58] In the pediatric setting monotherapy was supported by a meta-analysis that found similar clinical outcomes when antipseudomonal penicillin monotherapy was compared to antipseudomonal penicillin plus an aminoglycoside.[60] Therefore monotherapy is suggested for FN in pediatric patients who are clinically stable and who are treated at centers with a low rate of resistant pathogens.

Monotherapy regimens that have been evaluated in children include antipseudomonal penicillins such as piperacillin-tazobactam and ticarcillin-clavulanic acid, antipseudomonal cephalosporins such as cefepime, and carbapenems such as meropenem or imipenem. In two pediatric-specific evaluations, treatment failure, mortality rates, and adverse effects were similar when antipseudomonal penicillins were compared with antipseudomonal cephalosporins or carbapenems.[61,62] There are potential downsides of carbapenems and cefepime. Carbapenems were associated with more pseudomembranous colitis compared with other beta-lactam antibiotics in a large meta-analysis.[62] Cefepime was associated with increased all-cause mortality in another large meta-analysis when compared to other beta-lactam treated patients.[62] However, these findings were not replicated in other studies.[53,63] Consequently, cefepime remains an option for empiric therapy. Ceftazidime monotherapy lacks adequate coverage against viridans group streptococci and resistant gram-negative organisms and thus should not be used if these organisms are of concern.[64]

Empiric glycopeptides (e.g., vancomycin) are not routinely recommended. A largely adult meta-analysis of 14 randomized controlled trials (RCTs) illustrated that inclusion of a glycopeptide did not lead to a difference in success (if addition of glycopeptide in the control arm was not considered failure) but was associated with more adverse effects.[65] Empiric glycopeptides should be reserved for patients who are clinically unstable or who have signs or symptoms suggestive of a gram-positive infection.

Considerations for Low-Risk Patients with Fever and Neutropenia

Patients with FN who are at lower risk of adverse outcomes may be appropriate for a reduction in therapy intensity. Two strategies commonly considered are outpatient management and oral antibiotic administration. These two strategies are commonly used together, and in adults with low-risk FN, outpatient management with oral antibiotics is recommended for selected patients.[20,41] Some experts have expressed concern that these recommendations may not be generalizable to children.[66] However, over the last several years data have emerged related to efficacy and safety, costs, QoL and preference considerations for different management strategies in pediatric FN.

Efficacy and Safety of Outpatient Management and Oral Antibiotic Administration

The advantages of outpatient management include better QoL for children[67] and a reduction in costs,[68] nosocomial infection,[69] and acquisition of resistant microorganisms.[70] Outpatient management can be instituted at the onset of FN or after a brief period of hospitalization (step-down management). A meta-analysis synthesized the results of six RCTs, two of which were pediatric.[71] There was no difference in treatment failure with outpatient versus inpatient management (rate ratio [RR] 0.81, 95% CI 0.55 to 1.28) where the RR of less than 1 favored inpatient care. It is important to emphasize that failure was biased against outpatient care insofar as readmission was considered failure and this endpoint is applicable only to outpatients. No difference in mortality was demonstrated (RR 1.11, 95% CI 0.41 to 3.05). Results stratified by the two pediatric studies demonstrated similar findings as the overall analysis. The major concern with these data relates to the small number of children included; the two pediatric studies enrolled only 278 children. A subsequent systematic review combined all prospective randomized and nonrandomized pediatric trials that evaluated ambulatory or inpatient management within 24 hours of FN.[72] Among the 16 included studies, treatment failure was significantly less with outpatient management (15%) compared with inpatient management (27%, *P* = .04). There were no infection-related deaths among the 953 children treated as outpatients. Consequently, outpatient management appears to be a safe approach as long as appropriate patients can be selected and adequate follow-up monitoring is established. To institute outpatient management of FN, the institution must be able to identify low-risk patients and develop a program to monitor patients and expeditiously admit them in the case of deterioration. Social circumstances and travel considerations will dictate the feasibility of an ambulatory approach for a specific patient. The optimal frequency and nature of follow-up evaluations for children treated as outpatients for FN has not been determined, although daily clinic visits will rarely be feasible.

Oral antibiotic administration may be advantageous because it facilitates outpatient management, is usually less expensive, and does not require intravenous access. However, oral administration requires suspension formulation in younger children, and some children may refuse oral medication, particularly when they are unwell. There are two metaanalyses of RCTs that compared oral and parenteral antibiotic administration for FN; both did not restrict their review to low-risk patients. One included inpatient and outpatients (N = 2770),[73] whereas the other evaluated only outpatients (N = 1595).[71] Results were similar in both analyses, with no difference in treatment failure, mortality, or adverse effects of antibiotics by mode of administration. Results were similar when restricted to pediatric studies except for a trend toward lower risk of readmission for outpatient episodes treated with intravenous antibiotics compared with oral antibiotics (RR 0.52, 95% CI 0.24 to 1.09).[71] More data about the safety of oral administration were obtained from a meta-analysis of prospective pediatric trials, which instituted oral antibiotics within 24 hours of FN onset.[72] There was no difference in treatment failure among those who received oral versus intravenous antibiotics (20% versus 22%, *P* = .68). There was also no difference in the rate of antibiotic discontinuation resulting from adverse events (2% versus 1%, $P = .73$). No infection-related deaths were observed among the 676 children given oral antibiotics. To summarize, more readmissions were observed among children treated with oral antibiotics in the outpatient setting, although no difference in treatment failure or adverse events occurred and no child treated with oral antibiotics within 24 hours of FN onset died. Thus oral antibiotic administration may be appropriate if the health care team is confident that the child can tolerate this route reliably. Oral antibiotic regimens that have been used in pediatric FN include fluoroquinolone monotherapy, fluoroquinolone and amoxicillin-clavulanate, and cefixime.[72] One practical approach is to provide the first oral dose in the emergency or outpatient department to ensure that the child can tolerate oral administration of the planned empiric antibiotic. Discharge home would be contingent on successful administration. Even for children with low-risk FN who are managed as inpatients, oral administration may be advantageous because it is a more effective use of nursing resources and may facilitate early discharge depending on the reason for admission.

Costs

A pediatric cost-utility model demonstrated that outpatient management was the most cost-effective approach for children with low-risk FN.[68] Outpatient parenteral management was more cost-effective compared with outpatient oral management because of the higher rate of readmission among those who receive oral antibiotics. However, in sensitivity analyses, outpatient oral management may be more cost-effective depending on model assumptions. Inpatient management with intravenous antibiotic administration was the least cost-effective approach. These data suggest that outpatient management with intravenous or oral antibiotics is a better strategy for pediatric low-risk FN when probabilities, costs, and QoL are considered.

Preferences and Quality of Life

In implementing ambulatory and oral approaches for low-risk FN, consideration of patient and family preferences may facilitate program development. When asked which approach they preferred, approximately 50% of parents preferred inpatient intravenous management.[74,75] Both parents and children typically ranked inpatient intravenous management ahead of early discharge or ambulatory approaches.[75] A discrete choice experiment was used to assess preferences toward FN management.[76] Discrete choice experiment is an emerging method for the measurement of preferences in the face of multiple trade-offs in health care. Parents were willing to tolerate only 2.1 (95% CI 1.1 to 3.2) clinic visits weekly to accept outpatient oral management. If a program were developed with clinic visits three times weekly and a 7.5% chance of readmission, the probability of parental acceptance of such an ambulatory program was 43% (95% CI 39 to 48%).[76]

Estimation of QoL is also important to conduct cost-utility analyses, as previously described. In one study in which parents and health care professionals compared inpatient intravenous and outpatient oral management,[74] respondents rated child QoL as higher at home compared with hospital. Compared with parents, health care professionals overestimated QoL for children at home and underestimated QoL for parents in hospital. In another study in which parents rated their children's QoL with different FN management options, early discharge and outpatient intravenous therapy were associated with the highest anticipated QoL.[75]

These data suggest that parents may have reservations about an ambulatory oral antibiotic approach. In a qualitative study the major themes identified when parents make decisions regarding site of care and route of drug administration were convenience and disruptiveness for the family, the child's physical and emotional health, and modifiers of parental decision making.[77] Reasons for preferring an inpatient approach include the inconvenience of clinic visits, apprehension regarding whether they can adequately monitor their child, and concerns related to oral antibiotic administration. In summary, although the child's QoL is anticipated to be better with outpatient management, many parents prefer inpatient management.

Modification of Empiric Antibacterial Therapy

After therapy for FN has been initiated, the initial empiric regimen should be adjusted to provide appropriate coverage for any positive microbiology results or identified clinical focus of infection. In patients in whom empiric glycopeptides or dual gram-negative coverage was initiated, reassessment at 24 to 72 hours should be conducted. In the absence of a specific microbiological reason to continue these agents, they should be discontinued. In the event of persistent fever, careful evaluation for an undetected source of infection is important. In this setting modification of antibiotics, including addition of empiric vancomycin, is not warranted in children who remain clinically stable.[78] Children who clinically deteriorate warrant broadening of empiric antibacterial therapy to include coverage for resistant gram-positive, gram-negative, and anaerobic organisms.

Empiric antibiotics should be discontinued if cultures are negative, the child is clinically well, fever has resolved, and there is evidence of neutrophil recovery.[79] One randomized trial of pediatric low-risk patients found that cessation of antibiotics on day 3 irrespective of count recovery versus continuation of antibiotics was associated with similar outcomes.[80] However, *Enterobacter* bacteremia occurred in one child in the early cessation study arm. Consequently, it is reasonable to discontinue antibiotics on day 3 in low-risk children with FN who have become afebrile with negative cultures as long as careful monitoring is in place. In high-risk patients the optimal duration of antibiotic therapy is unknown in the setting of persistent profound neutropenia. A small study of 33 high-risk patients suggested that cessation of empiric antibiotics on day 7 is associated with bacteremia and poor infection outcomes compared with continuation for 14 days.[81] Thus continuation of empiric antibiotics for at least 14 days for high-risk FN in the absence of evidence of neutrophil recovery is a reasonable strategy.

Evaluation for Invasive Fungal Infection and Empiric Antifungal Therapy

Children with FN and persistent or recurrent fever that persists 96 hours or more after initiation of broad-spectrum antibiotics and who are at higher risk of IFI should undergo an evaluation for fungal infection, including careful physical examination, blood and urine cultures, and computerized tomography (CT) of the chest.[82-85] The role of routine CT sinuses and imaging of the abdomen have not been defined in the standard investigation of IFI, although routine CT sinuses should not be conducted in children 2 years of age or younger because of insufficient pneumatization of the sinus cavities.[79] In children with demonstrated pulmonary lesions, investigations may include bronchoalveolar lavage and lung biopsy, although fatal bleeding may occur with biopsy of any angioinvasive mold lesion. Thus the decision to biopsy requires careful consideration.

Empiric antifungal therapy should consist of either caspofungin or liposomal amphotericin B (L-AmB) because these two therapies are similarly effective and L-AmB is slightly better and less nephrotoxic than amphotericin B deoxycholate.[86-88] Empiric antifungal therapy may be discontinued at resolution of severe neutropenia if the patient is clinically well without evidence of an IFI.

PROPHYLACTIC STRATEGIES

Antibacterial Prophylaxis

The approach to routine antibacterial prophylaxis is uncertain because the overall balance of benefit and harm is not clear.[20] Most of the interest has been focused on fluoroquinolones because of broad spectrum of activity, relative preservation of gastrointestinal tract anaerobic flora, high concentration in the feces, systemic bactericidal activity, tolerability, and lack of myelosuppression. A large meta-analysis of RCTs composed mostly of adult subjects found that antibiotic prophylaxis decreased the risk of death (RR 0.67, 95% CI 0.55 to 0.81), infection-related mortality (RR 0.58, 95% CI 0.55 to 0.81), and bacteremia (RR 0.052, 95% CI 0.46 to 0.59).[89] Some uncertainty remains regarding whether these benefits are applicable to contemporary patients given the changing spectrum of gram-positive and gram-negative bacteria over time.

The decision to use routine antibacterial prophylaxis must include consideration of the negative consequences of prophylaxis. These consequences appear to be important to clinicians because most North American and German centers do not routinely use antibacterial prophylaxis for children with AML.[90] Potentially harmful effects include predisposition to IFI, *Clostridium difficile* colitis, and potential contribution to evolving antibiotic resistance. Additionally, the physician must consider the toxicities of the specific antibiotic chosen. The previously cited meta-analysis of antibacterial prophylaxis also showed that prophylaxis was associated with more adverse events (RR 1.57, 95% CI 1.33 to 1.86).[89] Parents also considered the frequency of administration, adverse effects, and costs in decision making related to antibacterial prophylaxis.[91]

Antifungal Prophylaxis

Because IFIs are relatively difficult to diagnose and effectively treat, there has been considerable interest in determining the effectiveness of a prophylactic approach, particularly in children undergoing allogeneic HSCT and children with AML, two populations at high risk for IFI.[92] Fluconazole prophylaxis was compared with placebo in two RCTs of allogeneic HSCT recipients.[93,94] Fluconazole decreased the occurrence of IFI because of a reduction in invasive candidiasis. Because children undergoing allogeneic HSCT are at risk for molds in addition to yeasts and because fluconazole does not provide any coverage against molds, there has been great interest in exploring the role of prophylactic antimold coverage. However, thus far agents with antimold activity, including micafungin, voriconazole, and amphotericin products, have not proved to have clinically significant advantages over fluconazole prophylaxis in the HSCT population.[95-97,98-100] Furthermore, some agents, such as itraconazole, showed a higher rate of toxicity leading to withdrawal[101] and agents such as amphotericin B led to infusion-related toxicities and renal toxicity.[102]

In pediatric AML a meta-analysis suggested that fluconazole significantly reduced the risk of IFI when the baseline rate was at least 15%.[103] The efficacy of itraconazole prophylaxis has also been explored. Although this agent has been shown to be effective compared with placebo or no therapy, no advantage over fluconazole or voriconazole has been demonstrated.[104-108] Posaconazole is an antifungal agent with broader antimold activity than voriconazole and thus represents a potentially better prophylactic option. In a randomized trial of patients with AML or myelodysplastic syndrome and prolonged neutropenia, posaconazole prophylaxis, when compared with fluconazole or itraconazole, reduced the rate of proven or probable IFI. Furthermore, overall survival rate was significantly better in posaconazole-treated patients.[109] However, only 16 adolescents between the ages of 13 and 18 years were included, and thus the generalizability of the results to children is limited. Furthermore, administration of posaconazole to children younger than 13 is challenging because of a lack of dosing information and the requirement to administer the drug orally with adequate food intake, which can be a challenge for children undergoing HSCT or those receiving chemotherapy for AML.

To better understand the contribution of mold-active prophylaxis, a systematic review of RCTs compared mold-active versus fluconazole prophylaxis in patients with cancer or those who underwent HSCT. Of 20 studies, children were included in four trials but only one trial was exclusively pediatric. Mold-active prophylaxis, when compared with fluconazole prophylaxis, significantly reduced the risk of IFI (RR 0.71, 95% CI 0.52 to 0.98), invasive aspergillosis (RR 0.53, 95% CI 0.37 to 0.75), and IFI-related mortality (RR 0.67, 95% CI 0.47 to 0.96). However, mold-active agents had significantly more associated adverse events leading to antifungal prophylaxis discontinuation or modification (RR 1.95, 95% CI 1.24 to 3.07). Mold-active prophylaxis did not influence overall mortality (RR 1, 95% CI 0.88 to 1.13).

Granulocyte and Granulocyte-Macrophage Colony Stimulating Factors

Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) are hematopoietic colony-stimulating factors (CSFs) that reduce the duration and severity of neutropenia in chemotherapy recipients.[110,111] In a meta-analysis of 16 RCTs of prophylactic use of CSFs in pediatric patients with cancer, the mean rate of FN in the control arms was 57% (range 39 to 100%).[112] CSFs reduced the rate of FN (RR of 0.80, 95% CI 0.67 to 0.95), documented infection (RR 0.78, 95% CI 0.62 to 0.97), and amphotericin B use (RR 0.50, 95% CI 0.28 to 0.87). There was no difference infection-related mortality (RR 1.02, 95% CI 0.34 to 3.06).[112] A meta-analysis of prophylactic CSF administration in the HSCT setting found that CSFs reduced the risk of documented infections (RR 0.87, 95% CI 0.76 to 1) but did not significantly reduce infection-related mortality (RR 0.76, 95% CI 0.41 to 1.44). Finally, a meta-analysis of 148 trials that included any cancer or HSCT population found that CSFs did not reduce short-term all-cause mortality (RR 0.95, 95% CI 0.84 to 1.08). A reduction of infection-related mortality was shown, but this did not reach statistical significance (RR 0.82, 95% CI 0.66 to 1.02). CSFs reduced documented infections (RR 0.85, CI 0.79 to 0.92), microbiologically documented infections (RR 0.86, 95% CI 0.77 to 0.96), and FN (RR 0.71, 95% CI 0.63 to 0.80).[113] Consequently, CSFs reduce FN and infections but do not influence overall survival. Whether CSFs should be administered therefore should depend on preferences, QoL considerations, and costs.

Prevention of Central Line–Associated Bloodstream Infection

A central line–associated bloodstream infection (CLABSI) can be defined as a bloodstream infection occurring in the presence of a CVL (present during the 48-hour period before development of the infection) and not related to infection at another site.[114] The most common causes of CLABSI are coagulase-negative staphylococci, *S. aureus*, *Enterococcus* spp., and *Candida* spp.[115] An evidence-based guideline supported by multiple agencies, including the Centers for Disease Control and Prevention, has been developed.[116] Recommendations included providing education and training focused on insertion and maintenance of CVLs and in particular indications for their use and competencies around insertion technique. Other recommendations were to use maximum barrier precautions and greater than 0.5% chlorhexidine skin preparation before CVL insertion and to critically assess the need for a CVL on an ongoing basis. Finally, the guideline recommended consideration of chlorhexidine-impregnated sponges and antimicrobial- or antiseptic-impregnated short-term CVL if other strategies for CLABSI reduction are not successful.

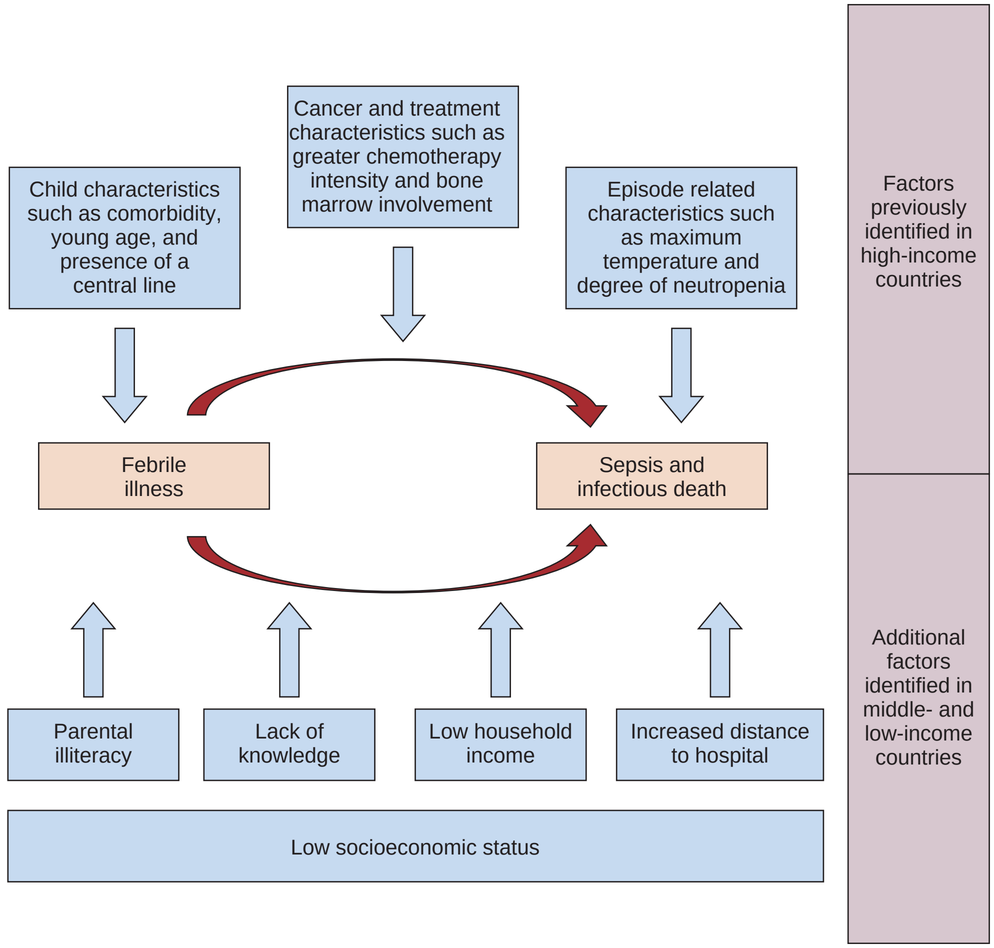
INFECTIOUS ISSUES IN PEDIATRIC CANCER PATIENTS IN LOW- AND MIDDLE-INCOME COUNTRIES

Children who live in low- and middle-income countries (LMICs) make up the majority of pediatric patients with cancer worldwide. As a group, they have not benefited from the same improvements in cancer outcomes compared with children who live in high-income countries.[117] Excessive infection-related mortality has contributed to this survival gap. In one study from El Salvador, treatment-related mortality (TRM) was responsible for 50% of deaths in children with ALL and AML;[118] the 2-year cumulative incidence of TRM was 12.5 ± 1.7% for ALL and 35.1 ± 6.4% for AML. The most important cause of TRM was infections. In a second study of FN among all cancer types in El Salvador, 12.3% of episodes were noted to result in death.[119]

Given the excessive risk of infectious toxicity, the identification of modifiable risk factors becomes paramount in this setting. Among children with ALL (but not AML), low monthly income and low parental education were associated with significantly higher TRM.[118] A subsequent prospective observational study in El Salvador sought to determine the association between socioeconomic status and time to assessment and treatment of fever and with rates of sepsis and infectious mortality.[120] Among 269 febrile outpatient episodes, the major source of delay was time from fever onset to decision to seek care, with 75% of parents waiting 5 hours or more. Once the decision to seek care had been made, the median time to reach the hospital was 1.8 hours. Parents who were illiterate had a 12- to 16-hour delay in deciding to seek medical care compared with parents who were literate. Once the decision to seek medical care had been made, parental literacy did not influence time to reach hospital. Maternal illiteracy was an independent risk factor for sepsis (OR 3.2, 95% CI 1.2 to 8.1), and lower annual household income was associated with infectious death (OR 13.9, 95% CI 1.6 to 119.1). These findings suggest that poor socioeconomic status translates into a delay in deciding to seek care and receiving medical attention in febrile children with leukemia. Figure 67-1 summarizes the different factors that affect the rates of infections and infection outcomes for children receiving cancer care in high-income countries and LMICs. The factors in high-income countries are predominantly treatment-related issues, whereas the factors in LMICs also include social and economic issues. Therefore any intervention employed to reduce TRM in LMICs must be tailored to these socioeconomic factors.

RECENT DIRECTIONS INVOLVING PRECLINICAL RESEARCH

Continued laboratory and translational investigation are critical to ensuring new advances in infectious diseases supportive care for future pediatric oncology patients. The fields of synthetic biology, immunotherapy, and gut mucosal immunology hold particular promise for



Cancer and treatment characteristics such as greater chemotherapy intensity and bone marrow involvement
Child characteristics such as comorbidity, young age, and presence of a central line
Episode related characteristics such as maximum temperature and degree of neutropenia
Factors previously identified in high-income countries
Febrile illness
Sepsis and infectious death
Parental illiteracy
Lack of knowledge
Low household income
Increased distance to hospital
Low socioeconomic status
Additional factors identified in middle- and low-income countries

* Based on a systematic review in pediatric oncology. Factors listed are illustrative and not meant to be exhaustive.

Figure 67-1 Factors associated with sepsis and infectious deaths in pediatric acute leukemia in low- and middle-income countries. *(From Gavidia R et al: Low socioeconomic status is associated with prolonged times to assessment and treatment, sepsis and infectious death in pediatric Fever in el salvador.* PLoS One *7:e43639, 2012.)*

novel methods of prevention and treatment of infectious diseases.

Synthetic biology is an emerging field focused on engineering biomolecular systems and cellular capabilities for a variety of applications, including the treatment of infections.[121] For example, bacteriophage (viruses that infect only specific bacteria) have been engineered to express a bacterial biofilm–degrading enzyme, dispersin B, that acts not only to rapidly degrade the biofilm matrix but also to kill 99.997% of the bacterial cells in the biofilm.[122] In another study synthetic adjuvants were designed by engineering bacteriophage to disrupt bacterial networks critical for antibiotic defense mechanisms, thereby resulting in significantly enhanced killing of bacterial strains by quinolones, beta-lactams, and aminoglycosides (in some cases a 5000-fold increase in killing).[123] Thus in the future bioengineered bacteriophages could help treat prosthetic device and CVL infections and also serve as adjuvants for treating antibiotic-resistant bacterial strains.

The use of immunotherapy in the prevention and treatment of infectious diseases is rapidly evolving. Adoptive transfer of antigen-specific T cells has proved to be an effective and powerful therapeutic tool in the prevention and treatment of viral infections (e.g., cytomegalovirus,[124] Epstein-Barr virus [EBV],[125] and adenovirus[126]) in immunocompromised hosts, but its use has been limited by the time needed to generate these cells. The technology has now advanced so that multivirus-specific (EBV, cytomegalovirus, adenovirus, BK, human herpes virus 6, RSV, and influenza) cytotoxic T lymphocytes (CTLs) can be generated within 10 days[127], and the possibility for using multivirus-specific CTLs for prophylaxis and treatment of viral infections, particularly in patients with leukemia and those undergoing HSCT, is encouraging.

The human microbiome, the aggregate of microorganisms that reside on and within the human host, has been shown to be critical for maintaining human immune function. Recent studies have shown that commensal microbes stimulate the gastrointestinal epithelium to produce antimicrobial proteins that act as a first line of defense against invading pathogenic bacteria.[128] When indigenous commensals are depleted after antibiotic administration, select pathogenic bacteria (e.g., vancomycin-resistant enterococci) can overgrow and cause invasive disease.[129] Interestingly, by stimulating intestinal Toll-like receptor (TLR) 4 by oral administration of lipopolysaccharide[129] or by stimulating TLR-5 with purified flagellin,[130] the antimicrobial protein RegIII gamma could be re-induced, and subsequently vancomycin-resistant enterococci levels in the murine gastrointestinal tract were significantly decreased and disseminated disease was prevented. As for human correlates, patients undergoing allogeneic HSCT uniformly developed reduced gut microbial diversity (as determined by deep 16S rRNA sequencing), with many patients exhibiting intestinal domination, defined as occupation of at least 30% of the microbiota by a single predominating bacterial taxon. As a predictor of outcomes, enterococcal domination increased the risk of vancomycin-resistant enterococcal bacteremia ninefold, and proteobacterial domination increased the risk of gram-negative bacilli bacteremia fivefold.[131] Thus methods for maintaining microbial homeostasis during chemotherapy and antibiotic therapies may provide a novel means for preventing colonization and dissemination of pathogenic microbes in cancer patients.

Expert and timely management of emergent situations is crucial in the practice of pediatric oncology. Although many emergencies are common across the spectrum of pediatric patients, such as seizure, respiratory arrest, and electrolyte abnormalities, others stem from the underlying cancer or cancer-directed therapy and are unique to this population of patients. These types of emergencies require special consideration and specific management to minimize adverse outcomes. Emergencies related to space-occupying lesions, metabolic derangements caused by breakdown of tumor cells, and disruption of the hematopoietic system by invasion of cancer cells all in some way relate to disruption of the normal function of a cell or organ as a result of the abnormal presence of cancer cells. This disruption can be rapidly progressive and life-threatening, as when patients with T-cell lymphoblastic leukemia present with a mediastinal mass and respiratory compromise. The treatments directed toward cancer also carry significant toxicities and can result in uniquely emergent complications. Many chemotherapy agents result in a state of significant immune compromise and put patients at risk for unusual or opportunistic infections, as well as fulminant presentations of infection with more common organisms. All chemotherapy drugs carry extensive profiles of possible adverse effects, and errors of administration or dosage can magnify toxicity; any available therapeutic interventions must be administered immediately. Appropriate management of an emergent pediatric oncologic situation requires a clear understanding of the specific underlying disease process and of the effects and consequences of cancer-directed therapies.

Symptoms in children who present with new diagnoses of cancer or are receiving cancer treatment are myriad. Therefore recognition of an emergency is not always straightforward, particularly in the young pediatric population, for whom obtaining an accurate history can be challenging. It is therefore imperative that the clinician maintain a high level of vigilance for the presentation of potentially life-threatening situations. A child with cough and mild respiratory distress is most likely to have a viral infection, but these symptoms also might be consistent with a child presenting with a marked mediastinal mass, developing leukostasis syndrome, or the onset of Pneumocystis pneumonia. A complaint of lower back pain in a child may relate to new physical activity or could represent developing spinal cord compression from a tumor. Pediatric oncologists need to be familiar with all pediatric oncologic emergent situations to evaluate and manage

Box 68-1 **Commonly Encountered Pediatric Oncologic Emergencies**

Veno-occlusive disease
Intrathecal chemotherapy overdose
Central nervous system events such as seizure or CVA
Severe allergic reactions to chemotherapy agents or blood products

these high-risk patients appropriately. Rapid and appropriate triage of patient complaints is critical, because overlooked diagnoses, as well as inaction or inappropriate action, can have severe consequences.

Grouping of some emergent pediatric oncologic conditions into disease- and treatment-related events is presented in Box 68-1. Clear overlap exists among the conditions listed; for example, tumor lysis syndrome (TLS) can occur on presentation with a new diagnosis of leukemia or high-grade lymphoma, but it can be markedly worsened by initiation of chemotherapy. Similarly, superior vena cava syndrome (SVCS) can result from a new or recurrent presence of a mass lesion or as a complication of an indwelling catheter placed to deliver antineoplastic therapy. In this chapter our discussion will focus on several emergent situations unique to pediatric oncology patients, with a review of available data and overviews of current management strategies. The topics addressed in the chapter are anterior mediastinal mass, increased intracranial pressure, spinal cord compression, hyperleukocytosis and leukostasis, TLS, and selected chemotherapy toxicities. Several topics unique to the pediatric oncology patient are covered elsewhere in this text and will not be readdressed in this chapter (e.g., management of fever and neutropenia, typhlitis, veno-occlusive disease, all-*trans*-retinoic acid syndrome, transfusion medicine, and pain management). Situations that can occur in the pediatric oncology patient but that are not unique to this population, such as seizure, cerebral vascular injury, disseminated intravascular coagulation, and pancreatitis, will not be discussed here.

Although optimal management of many of these emergent situations has been difficult to study, given the relatively small number of patients presenting to each institution, a literature is evolving for many of these topics. Many institutions have established clinical practice guidelines to help manage the most common pediatric oncologic emergencies. Clinical practice guidelines provide uniform standards for management but must allow for adaptations for each specific clinical scenario. Uniform use of clinical guidelines with collection and analysis of outcomes has the potential to guide improvements in clinical practice.

ANTERIOR MEDIASTINAL MASSES

Definition

A commonly encountered oncologic emergency is the entity of anterior mediastinal mass. A clinician should always consider this entity in the differential diagnosis of a pediatric patient with new respiratory distress and must consider evaluation, even in asymptomatic patients presenting with any of the variety of cancers known to be associated with the occurrence of anterior mediastinal masses.

Space-occupying lesions occurring in the anterior mediastinum can impinge on vital structures, causing significant cardiac or airway compromise. The anterior mediastinum is defined as the anatomic compartment bounded by the sternum, thoracic inlet, and anterior border of the heart.[1] The presence of a mass in this region can cause SVCS, tracheobronchial compression, or compression of the heart or pulmonary vessels. The term *superior mediastinal syndrome* (SMS) has been used to denote the combination of great vessel and tracheobronchial tree compression. However, because these phenomena may be overlapping, particularly in the pediatric population, the terms SVCS and SMS are often used interchangeably.

Neoplasms that cause anterior mediastinal masses in the pediatric population and are associated with SVCS and/or tracheal compression include non-Hodgkin lymphoma (NHL), acute lymphoblastic leukemia (ALL), and Hodgkin lymphoma (HL),[2] as well as neuroblastoma, paraganglioma, germ cell tumors, sarcoma (including myeloid sarcoma), thymoma, desmoplastic round cell tumor, lymphangioma, inflammatory myofibroblastic tumor, and thyroid and parathyroid carcinaomas.[3-10] In a retrospective review of children with mediastinal masses treated at the Mayo Clinic, NHL and HL represented the majority of malignant causes of anterior mediastinal masses, although this review did not include patients with leukemia.[10] In a report on 3721 children with cancer treated at St. Jude Children's Research Hospital over a 15-year period, 24 children had superior vena cava (SVC) obstruction at initial presentation or with disease recurrence. Patients presenting with SVC obstruction at initial presentation included eight children with NHL, four with ALL, two with HL, one with neuroblastoma, and one with yolk sac tumor.[9] In contrast, in the adult population, small cell bronchogenic carcinoma is the most common underlying diagnosis associated with SVCS.[11]

SVCS was first described in a patient with a syphilitic aneurysm of the aorta in 1757.[12] The SVC is a thin-walled vessel with blood flowing under low pressure and is easily compressible by the enlargement of surrounding structures in the thorax. In persons with SVCS, compression and obstruction of the SVC cause restriction of blood return to the right atrium and impaired venous drainage from the upper extremities, head, and neck. Occlusion of

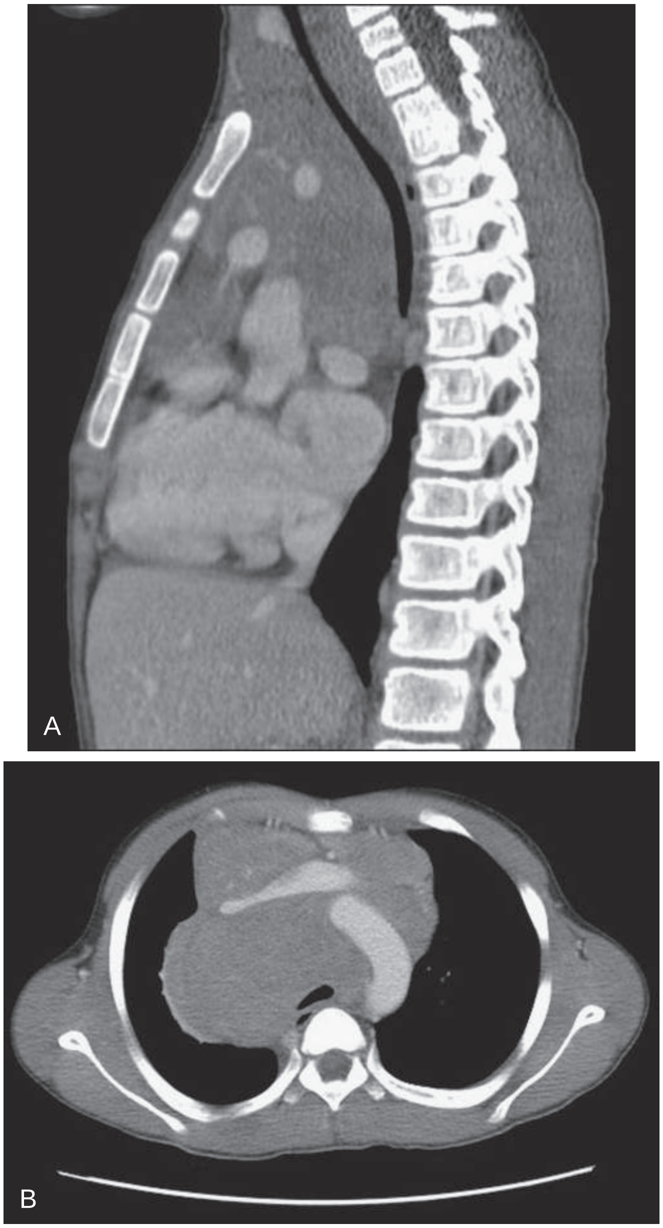

Figure 68-1 A chest computed tomography scan of a patient with Hodgkin disease. Sagittal (**A**) and axial (**B**) images show the significant effects of the mass on structures within the mediastinum, with marked narrowing of the trachea and superior vena cava. Remarkably, the patient was symptomatic only with exercise.

the SVC by thrombus—for example, as a complication of a central venous line—can also result in SVCS. Just as the SVC can be compressed by an anterior mediastinal mass, the trachea and main stem bronchi in children are relatively compressible and have smaller intraluminal diameters compared with these structures in adults, making the pediatric patient with an enlarging mass susceptible to respiratory compromise (Fig. 68-1).[10]

Clinical Presentation

Children with SMS can present with a constellation of signs and symptoms related to SVC and airway obstruction, including swelling, plethora, venous engorgement of the face, neck, and upper extremities, cough, hoarseness, orthopnea, cyanosis, anxiety, syncope, and altered mental status.[13,14] The child can present in extremis, with shock caused by cardiac compromise, or the child can present with respiratory failure, which more commonly occurs in malignancies with a higher growth fraction such as B- or T-lymphoblastic or mature B-cell lymphomas. Conversely, patients with more indolent tumors, such as HL, can present with impressively large masses and surprisingly little symptomatology (Fig. 68-2). Symptoms are often more profound with the patient in the supine position and may improve in the upright or prone position. In the supine position, thoracic volume is decreased because of decreased rib cage dimension and diaphragm position. In addition, blood flow to the mass itself can increase, causing further expansion of the mass.[1] Therefore pursuing testing such as computed tomography (CT) scanning in the supine position should be carefully considered, and patient tolerance of supine positioning should be evaluated before initiating cross-sectional imaging. Patients who are unable to tolerate supine positioning may require decubitus or prone positioning if CT evaluation is necessary during the initial workup, and some patients with extreme compression may not be able to tolerate any horizontal positioning prior to emergent cytoreductive therapy.

An anterior mediastinal mass may be suspected on the basis of medical history and physical examination and can be identified on a chest radiograph. Identifying patients at greatest risk for anesthetic complications is important in planning the diagnostic evaluation. Procedural sedation and anesthesia pose particular risks for

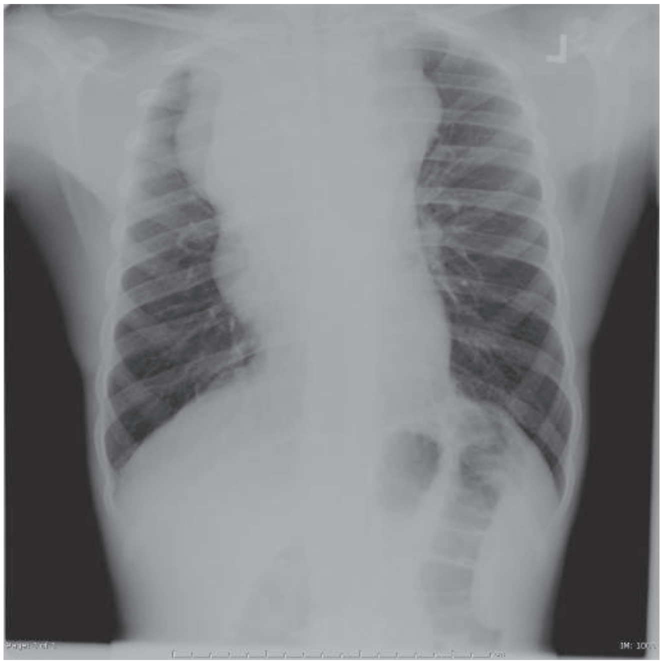

Figure 68-2 A chest radiograph of a patient with Hodgkin disease showing a markedly enlarged mediastinum. The patient had a several-month history of intermittent cough and had only mild respiratory symptoms at presentation.

patients with an anterior mediastinal mass, with the potential for cardiopulmonary collapse and death.[13-15] A patient whose respiratory status is stable while awake, with spontaneous respirations, may experience significant obstruction when anesthesia is induced. General anesthesia alters ventilatory mechanics, decreasing inspiratory muscle tone and functional residual capacity of the lung.[16] Chest wall tone is decreased by neuromuscular blockade. Airways are more compressible because of bronchial smooth muscle relaxation.[14] Positive pressure ventilation may further restrict an already narrowed airway.[17] In addition, general anesthetic agents can have negative inotropic effects and may contribute to decreasing cardiac output, precipitating hypoxemia, hypotension, or even cardiac arrest in patients with compression of the great vessels.[18]

Respiratory symptoms occur in 40% to 60% of children with anterior mediastinal masses, but correlation of symptoms with anesthetic risk can be challenging.[14,19] Orthopnea has been associated with increased anesthetic risk.[19,20] Posterior anterior and lateral chest radiographs can demonstrate tracheal compression but may not detect all cases.[19,21] CT can provide additional anatomic information, and patients with less than 50% of expected tracheal cross-sectional area on CT have been shown to be a high-risk group.[14,19] However, obstruction distal to the trachea may be more difficult to appreciate. Authors of a prospective study assessing tracheal area and pulmonary function testing have found that inducement of general anesthesia can be used safely in children who meet the minimum criteria of a tracheal area larger than 50% and predicted peak expiratory flow rate (PEFR) greater than 50%. Thirty-one children with mediastinal masses underwent pulmonary function testing in the sitting and supine positions along with CT prior to undergoing 34 surgical procedures. For children with less than 50% of predicted cross-sectional tracheal area (or with less than 50% of PEFR), only local rather than general anesthetic agents were used. Five patients had predicted tracheal areas larger than 50% but had a low PEFR and thus only local anesthetic agents were used. No intraoperative complications occurred in patients receiving anesthetic drugs when these criteria were used.[22]

Evaluation and Imaging

A definitive diagnosis is needed to initiate tumor-specific therapy, and the least invasive diagnostic methods possible should be pursued. If the peripheral blood smear is abnormal, a bone marrow aspiration or biopsy with use of a local anesthetic may prove sufficiently diagnostic. A biopsy of a peripheral lymph node, if present, may prove diagnostic. Serum α-fetoprotein or β-human chorionic gonadotropin may be positive in patients with mediastinal germ cell tumors, and these tests can be performed rapidly in many institutions. If a pleural effusion is present, pleural fluid aspiration may be possible with use of local anesthesia and may provide fluid for pathologic review and immunophenotypic and cytogenetic evaluation (Fig. 68-3).[23] Some patients whose only source of potential diagnostic tissue is the mediastinal mass will be able to tolerate percutaneous needle biopsy with use of a local anesthetic and anxiolytic-only sedation.

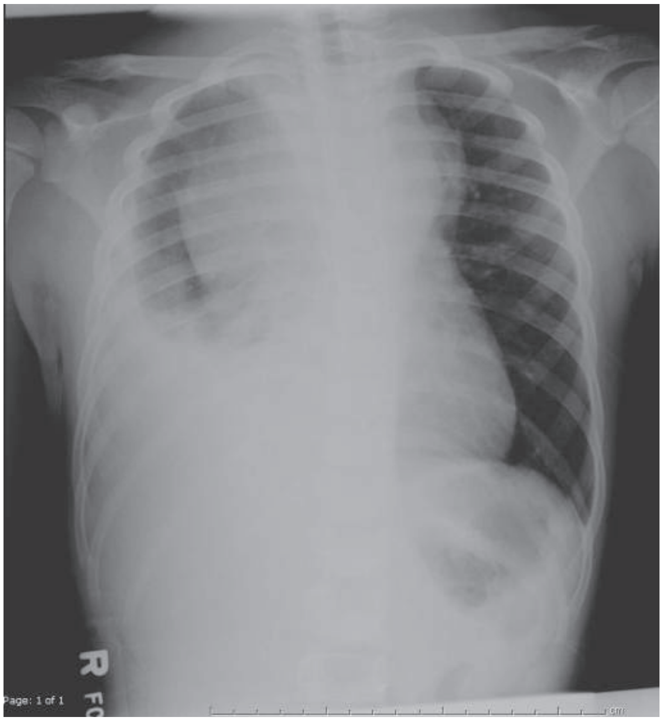

Figure 68-3 A chest radiograph of a patient who presented in near extremis, with facial swelling, plethora, and significant respiratory distress. The patient had a large anterior mediastinal mass and marked pleural effusion. T-cell lymphoblastic lymphoma was diagnosed from the pleural fluid.

An accurate tissue diagnosis allows for initiation of the optimal specific treatment regimen. For many patients with anterior mediastinal masses, a general state of anesthesia will be able to be induced safely.[24] However, the cases of patients in extremis or those with rapidly evolving respiratory compromise who require sedation or inducement of general anesthesia are particularly challenging to manage. When proceeding with general anesthesia, some persons have advocated the preservation of spontaneous respiration when at all possible, avoidance of the use of muscle relaxants, being prepared to change the patient's position, and having an expert bronchoscopist and emergency cardiopulmonary bypass available.[15] Use of bilevel positive airway pressure for safe anesthesia in these settings has been reported recently.[25] Successful suprasedative dosing of dexmedetomidine has also been reported.[26] Use of extracorporeal membrane oxygenation in persons with anterior mediastinal masses who are experiencing cardiopulmonary failure has been reported.[27] Use of inhaled heliox, a helium-oxygen mixture, has been advocated in case reports to decrease resistance to airflow in obstructed airways, although its use in the setting of anterior mediastinal masses has not been studied.[28]

In recent years the surgical literature has included an increased focus on novel operative techniques to allow safe biopsy and/or resection in patients with large anterior mediastinal masses. Percutaneous biopsy has long been a standard approach in patients too unstable for inducement of general anesthesia, but advances in imaging technique allow for additional applications of this methodology, such as real-time ultrasound fusion with CT for biopsy guidance.[29] Additional modalities recently described as successful in a majority of patients include awake video-assisted thoracoscopic biopsy, the hemiclamshell approach, and the Chamberlain procedure (also known as anterior mediastinotomy).[30-32]

Treatment

In some clinical situations the risk of proceeding with diagnostic procedures is considered too great, and empiric therapy aimed at reducing the mass must be initiated. Emergent treatment modalities include radiation, intravenous steroids, and combination chemotherapy. Radiation has traditionally been used in emergency management of anterior mediastinal masses, because most lymphomas are radiosensitive. Daily radiation doses are based on those used for the presumed diagnosis that best fits the clinical data. Depending on the radioresponsiveness of the mass, prebiopsy radiation treatment will frequently obscure the tissue diagnosis, even with low-dose radiation therapy. Loeffler and colleagues[33] reported that in 8 of 10 patients younger than 30 years who underwent emergent prebiopsy radiation for a mediastinal mass, a tissue diagnosis could not be established because of uninterpretable pathologic specimens. Also of concern in the pediatric population is a risk of postradiation respiratory deterioration caused by swelling of the trachea after radiation. Concurrent administration of a steroid (e.g., dexamethasone at a dosage for airway edema, 0.5 to 2 mg/kg/day in divided doses every 6 hours) can be considered with the goal of preventing this complication but may also contribute to obscurity of the diagnosis because most untreated lymphomas are sensitive to steroids.

The emergent use of empiric chemotherapy includes the use of intravenous (IV) steroids or combination chemotherapy. Steroid therapy should be considered in the emergent management of proven or presumed ALL or lymphoblastic lymphoma. Careful attention must be directed to fluid management given concerns for TLS in the patient with the potential for cardiovascular compromise. Consideration of the use of rasburicase may be warranted. Steroid dosing based on ALL treatment protocols can be used (e.g., methylprednisolone, 32 to 48 mg/m^2/day IV, divided every 8 to 12 hours). Steroid therapy may also be effective in the setting of other malignancies because of its potent antiinflammatory effect. Other chemotherapeutic agents for consideration in the emergent management of anterior mediastinal mass include cyclophosphamide, vincristine, and anthracyclines. Just as radiation may eliminate the ability to establish a definitive diagnosis, steroid therapy has also been reported to inhibit accurate diagnosis.[13] Without a definitive pathologic diagnosis, continued treatment of the patient for the presumed diagnosis that best fits the clinical data has been advocated. Masses that are not responsive to the previously described emergent therapies may require surgical intervention.

Conclusions

The evaluation of a child with a suspected anterior mediastinal mass or SVCS should be initiated rapidly once the diagnosis is considered to be a possibility. Great variability in the course of evaluation and treatment may be encountered, depending on the specifics of each clinical situation, including the clinical stability of the patient and the underlying diagnosis. A representative evaluation and treatment algorithm published in 2008 is outlined in Figure 68-4.[34] The clinician must adapt his or her care to the particular circumstances of the individual patient.

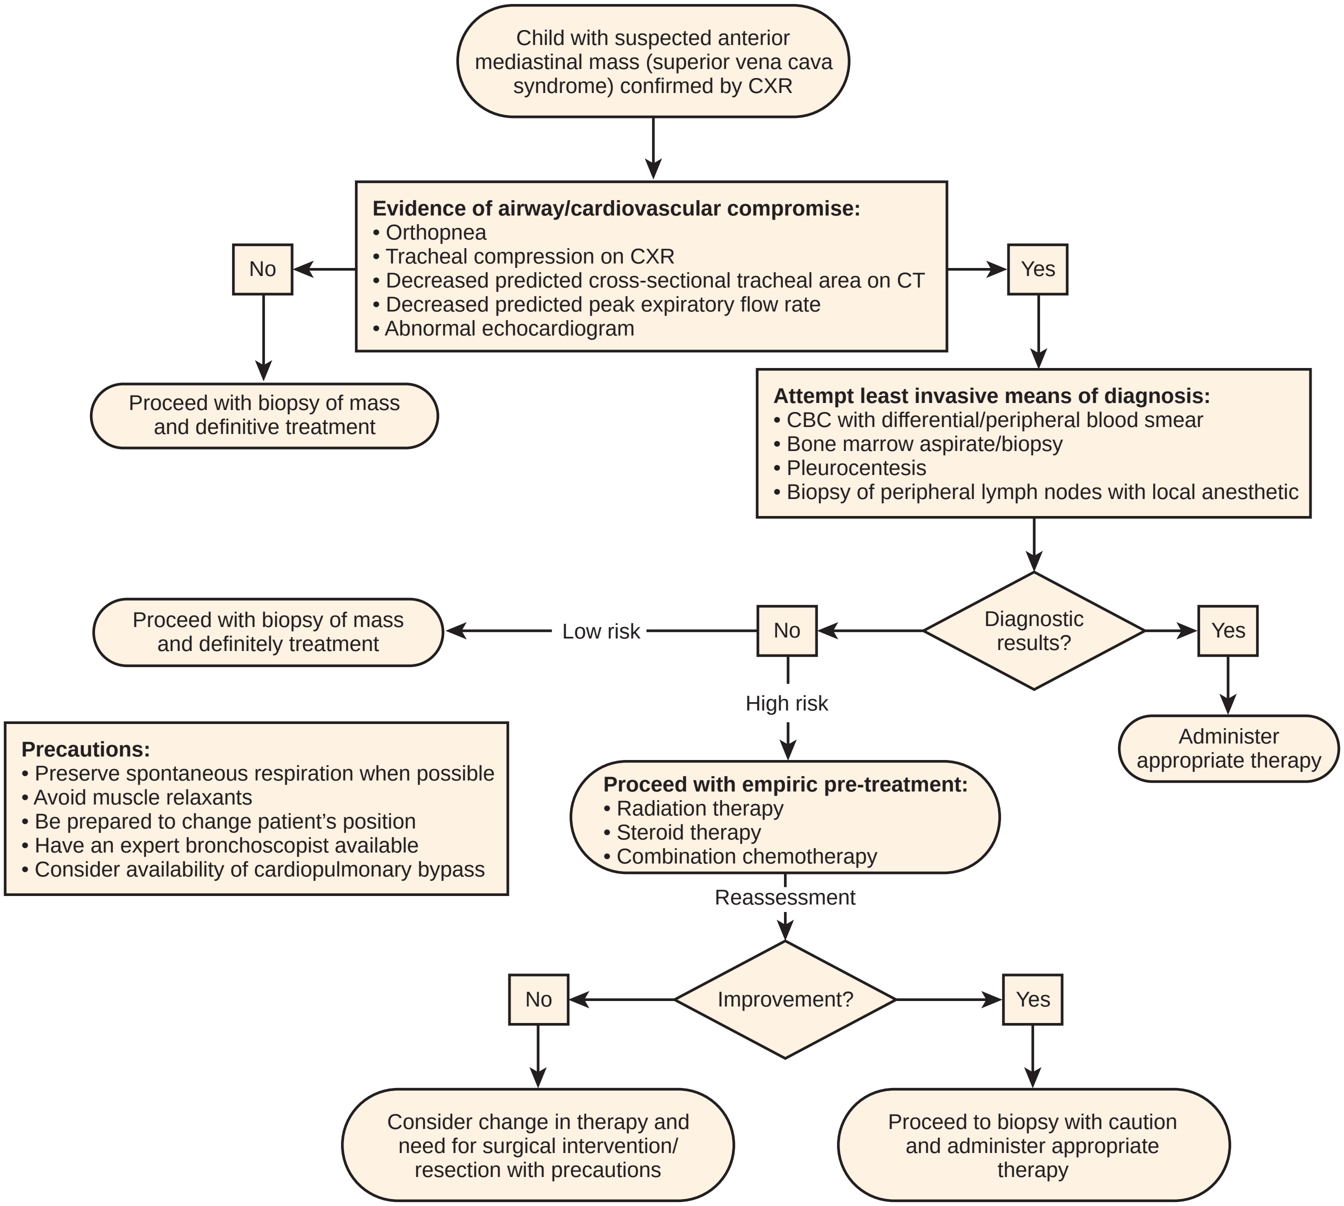
SPINAL CORD COMPRESSION

Spinal cord compression is overall a rare event in children, but several studies have shown an incidence of up to 5% in children with cancer.[35] The most frequent occurrence of spinal cord compression in children with cancer is during the initial presentation of the malignant process (67% of the time).[36] Although such a presentation often occurs with widely disseminated disease, spinal cord compression can also occur with a singular lesion as the initial presentation of a new diagnosis of cancer. In this scenario, along with preservation or restoration of lost neurologic functioning, proper diagnosis of the cancer through adequate tissue sampling is a management priority. Procurement of sufficient tissue for specialized testing and possible study enrollment is a lesser priority but still should be thoughtfully considered in the overall management plan. Spinal cord compression is also encountered in patients with relapsed and refractory disease, again as a single metastatic lesion or as widespread metastatic disease. In such situations, management strategies must take into account the likelihood of cure, the effect of interventions on the patient's quality of life, and the role of palliation.

The majority (71%) of tumors that cause spinal cord compression are extradural.[36] More than 50% of tumors causing spinal cord compression are found to be neuroblastoma, soft tissue sarcomas, Ewing sarcoma, or rhabdomyosarcoma. A wide variety of other tumors have been reported as causes of spinal cord compression and must be considered in the differential diagnosis. Tumors reported to date include osteosarcoma, Wilms tumor, metastatic central nervous system tumors, meningioma, pleuropulmonary blastoma, juvenile xanthogranuloma, adrenocortical carcinoma, acute myelogenous leukemia (AML), and lymphoma.[37-40]

Clinical Presentation

Back pain is the most common presenting sign of spinal cord compression and was present in 94% of 70 pediatric patients presenting with solid tumors and spinal cord compression.[36] Because recurrent back pain without known injury is a fairly uncommon complaint in children, spinal lesions and spinal cord compression should always be considered in the differential diagnosis of this complaint, even in the absence of neurologic findings. In pediatric patients known to have cancer, the index of suspicion must be particularly high. Any delay



Child with suspected anterior mediastinal mass (superior vena cava syndrome) confirmed by CXR
Evidence of airway/cardiovascular compromise:
• Orthopnea
• Tracheal compression on CXR
• Decreased predicted cross-sectional tracheal area on CT
• Decreased predicted peak expiratory flow rate
• Abnormal echocardiogram
No
Yes
Proceed with biopsy of mass and definitive treatment
Attempt least invasive means of diagnosis:
• CBC with differential/peripheral blood smear
• Bone marrow aspirate/biopsy
• Pleurocentesis
• Biopsy of peripheral lymph nodes with local anesthetic
Diagnostic results?
No
Yes
Low risk
Proceed with biopsy of mass and definitely treatment
High risk
Administer appropriate therapy
Precautions:
• Preserve spontaneous respiration when possible
• Avoid muscle relaxants
• Be prepared to change patient's position
• Have an expert bronchoscopist available
• Consider availability of cardiopulmonary bypass
Proceed with empiric pre-treatment:
• Radiation therapy
• Steroid therapy
• Combination chemotherapy
Reassessment
Improvement?
No
Yes
Consider change in therapy and need for surgical intervention/ resection with precautions
Proceed to biopsy with caution and administer appropriate therapy

in diagnosis of spinal cord compression may contribute significantly to morbidity. A thorough physical examination should accompany a complete history. The history should include characterization of pain, including onset and duration. Neurologic findings, if present, will vary, depending on the spinal level of the lesion and the degree of compression. In their series of children with systemic cancer and spinal cord disease, Lewis and coworkers[35] noted that localized spine tenderness is the most reliable clinical finding. A spectrum of ataxia, gait disturbance, and paraplegia can be observed. Sphincter dysfunction is most commonly seen as urinary retention or constipation. Localization of the level of epidural cord compression along the spine is suggested by the specific effects on strength, tendon reflexes, sensory level, Babinski reflex, sphincter abnormalities, and rate of progression (Table 68-1).[35,41]

Evaluation and Imaging

When the possibility of spinal cord compression is considered, immediate evaluation should be undertaken. Spinal radiography is often the first-choice modality because it is quickly and easily undertaken. Plain films may be able to provide valuable clinical information rapidly, but one must be aware that they are positive in only approximately 30% of patients with spinal cord compression.[35] The presence of a compressive spinal lesion may be seen on a radiograph as a paraspinal soft tissue mass. In cases of neuroblastoma, calcifications are often present within the paraspinal mass. Classically,

TABLE 68-1 Epidural Cord Compression: Clinical Localization

	LOCATION		
Sign	**Spinal Cord**	**Conus Medullaris**	**Cauda Equina**
Weakness	Symmetrical; profound	Symmetrical; variable	Asymmetrical; may be mild
Tendon reflexes	Increased or absent	Increased knee; decreased ankle	Decreased; asymmetrical
Babinski	Extensor	Extensor	Plantar
Sensory	Symmetrical; sensory level	Symmetrical; saddle	Asymmetrical; radicular
Sphincter abnormality	Spared until late	Early involvement	May be spared
Progression	Rapid	Variable; may be rapid	Variable; may be slow

Modified from Lewis DW, Packer RJ, Raney B, et al: Incidence, presentation, and outcome of spinal cord disease in children with systemic cancer. Pediatrics *78:438–443, 1986.*

neuroblastoma invading the spinal canal and intervertebral foramina may be visualized as a dumbbell-shaped lesion surrounding the spine. Other tumors can also have this appearance, emphasizing the importance of obtaining adequate tissue for diagnosis (Fig. 68-5). In many spinal lesions, lytic or sclerotic changes in adjacent bone are often observed on a radiograph. Diagnostic widening of interpeduncular distances and enlargement of the neural foramina can sometimes also be observed on radiographs.

Emergent magnetic resonance imaging (MRI) is essential when plain radiographs are negative and clinical suspicion still exists. MRI is also necessary for further delineation of lesions observed on plain radiographs. MRI has become widely accessible and thus it has replaced the previously used techniques of radionucleotide bone scanning, spinal CT with intrathecal contrast, and lumbar myelography. MRI offers the advantage of increased accuracy and a less invasive nature than previously used modalities. Careful comparison of axial, coronal, and sagittal images can help categorize spinal tumors as extradural, intradural-extramedullary, or intramedullary, thereby aiding in the differential diagnosis.[42] MRI sequences with and without use of gadolinium should be obtained for patients being evaluated for spinal cord compression. Contrast enhancement is less helpful for extradural tumors than for intradural-extramedullary or intramedullary lesions. Fat suppression techniques are most helpful for evaluating extradural lesions. It should also be remembered that it is important to image the entire spine to identify the possibility of involvement at several levels, even if the physical examination has localized the most likely area of compression.

MRI can also accurately detect compression and dislocation of the spinal cord. Coronal images can elucidate the degree of cranial and caudal extension on the intraspinal component of a mass lesion. Because of increased cellularity and high nuclear-to-cytoplasmic ratio, lesions are usually isodense to hypodense on T2-weighted images.[43] Cord edema can be seen as a hyperintense signal in T2-weighted images. Contrast enhancement is generally marked in the presence of intraspinal lesions. Diffusion tensor imaging has been recently described as a potentially beneficial additive sequence.[44]

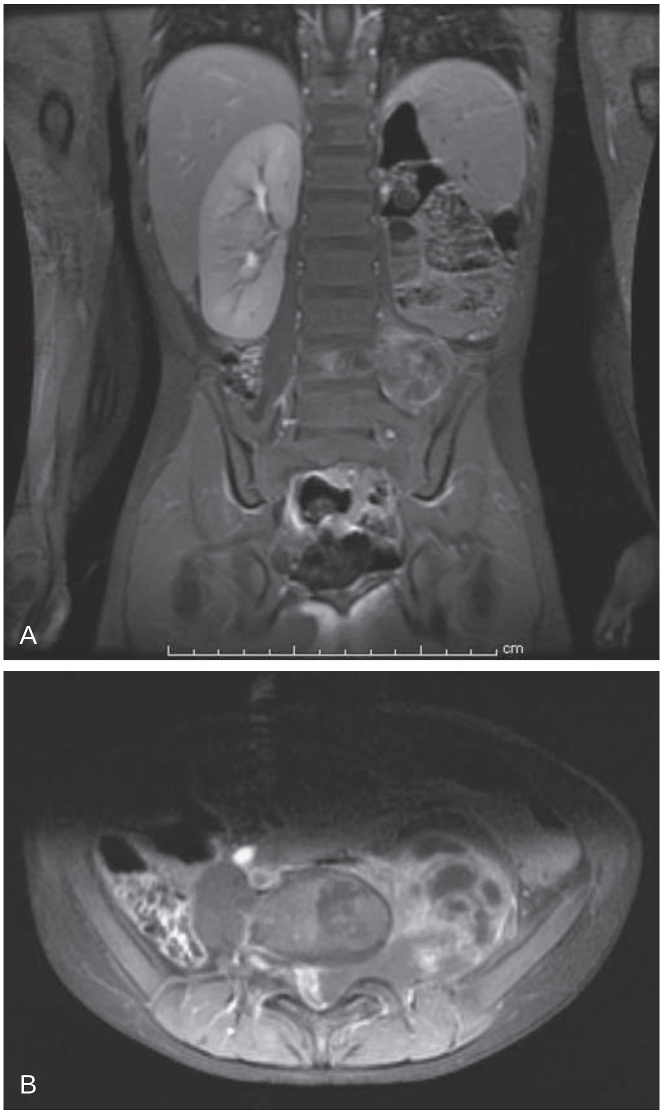

Figure 68-5 Magnetic resonance imaging after administration of gadolinium demonstrates a soft tissue retroperitoneal mass at the level of L4 with a dumbbell appearance on both coronal (**A**) and axial (**B**) views. The patient presented with a short history of leg pain and limp that progressed to the inability to ambulate, 2 years after the completion of therapy for Wilms tumor with a favorable histology.

If the clinical situation allows time for further radiologic evaluation, CT with bone windows can provide complementary information to MRI findings. Detailed information on bone architecture and cortical appearance is better obtained via CT.

Treatment

Treatment options for a patient presenting with spinal cord compression include surgery (laminectomy or laminotomy), chemotherapy, steroid therapy, and radiation therapy. The best choice of initial therapy will vary depending on the clinical situation. In many clinical situations use of more than one modality may be appropriate, and in some situations it is appropriate for more than one modality to be used simultaneously. The complexity of the choice of the best initial therapy stems largely from multiple competing therapeutic goals—the desire to act quickly to prevent further loss of neurologic function, the need to make an accurate diagnosis with sufficient biologic information for assignment of appropriate treatment, the hope of regaining any lost function existing at presentation, and the concern regarding the late effects of the available emergent treatment modalities. After providing a brief overview of the basic treatment options, we will present the conclusions of several clinical studies.

Surgery

Laminectomy is the most common surgical approach to relieve spinal cord compression caused by a solid tumor. Laminectomy involves removal of the bony arch, or lamina, of a vertebra. This procedure is often combined with biopsy and/or debulking of the tumor. The advantage of a laminectomy is the rapid decompression of the spinal cord. Laminectomy is generally accepted as the most likely modality to stabilize or improve lost neurologic function. Another significant advantage of laminectomy is the procurement of tumor tissue for proper histologic diagnosis and the option of obtaining tissue for relevant biology studies or possible protocol enrollment. The disadvantage of laminectomy is the high risk for late effects, with a significant percentage of patients experiencing kyphosis or scoliosis. Depending on the degree of spinal cord injury and how long symptoms have been present, laminectomy may not provide an advantage compared with treatment with chemotherapy only and may expose the child to risks of the surgical procedure and greater risks of long-term orthopedic sequelae.

The technique of osteoplastic laminotomy involves removal of part of the lamina above and below an affected nerve, with subsequent bracing for a period of 6 to 8 weeks. Although historically this technique is not commonly used, it may offer a decreased incidence of long-term sequelae and may be considered by the surgeon. Minimally invasive thoracoscopic approaches for decompression have been described.[45-48] Additionally, percutaneous approaches for decompression are increasing reported.[49,50]

Chemotherapy

Chemotherapy can be used successfully to reduce some neoplastic masses that cause spinal cord compression. Use of chemotherapy has been most studied in cases of neuroblastoma or Ewing sarcoma that present with spinal cord compression, and chemotherapy has been used successfully to treat germ cell tumors as well.[51] In the rare cases of leukemic or lymphomatous infiltrates, chemotherapy is the clear standard initial therapy once the diagnosis has been established.

Advantages of upfront chemotherapy for lesions causing spinal cord compression are that chemotherapy is anatomically noninvasive and long-term surgical consequences may be avoided. In addition, patients may proceed with tumor-specific therapy without the need for delay from postoperative healing. However, the use of chemotherapy depends on first establishing an accurate pathologic diagnosis. In cases of metastatic tumor, it may be possible to make a diagnosis by biopsy of other primary or metastatic lesions. Identifying isolated paraspinal masses can be more diagnostically difficult. If surgery is avoided completely and chemotherapy is started presumptively, the possibility of an incorrect diagnosis will exist. Also, if no tissue is obtained, even though an isolated paraspinal mass may eventually be diagnosed as neuroblastoma on the basis of elevated urine catecholamine levels or positive metaiodobenzylguanidine activity, the opportunity to obtain valuable biologic information, such as histology, v-myc avian myelocytomatosis viral oncogene neuroblastoma derived homolog *(MYCN)* status, and other cytogenetic and molecular markers used to direct therapy could be lost.

In patients who experience spinal cord compression in the setting of relapsed disease, the choice of using chemotherapy rather than surgery or radiation therapy can become more complex, because the rate and overall likelihood of response can be substantially decreased in previously treated patients. Radiation therapy or surgeries may have been used previously and may limit these options in a relapse setting. Such clinical situations must be carefully weighed individually. The decision to initiate chemotherapy rather than to use surgery, radiation therapy, or comfort palliation must include consideration of the patient's overall chance of long-term cure, the history of treatment and response, and most importantly, the goals of treatment of the patient and family and the desired level of intensity of therapy.

In the patient with a new presentation of cancer, the choice of a chemotherapy regimen must be based on a clear identification of the malignant process. Once a diagnosis is known and a decision has been made to avoid surgery or radiation and commence with chemotherapy, standard frontline therapy for the malignancy that has been identified is accepted as the best initial chemotherapy in patients with spinal cord compression.

Dexamethasone

Dexamethasone is routinely recommended throughout the literature for the treatment of pediatric spinal cord compression. It is theorized that decreased swelling of the cord will help minimize neurologic damage through minimizing the effect of vasogenic edema and venous congestion. In a review of the adult literature compiled to create an evidence-based guideline for the emergency treatment of extradural spinal cord compression in adult patients, Loblaw and Laperriere[52] reviewed the available studies on the use of dexamethasone. They found strong evidence to support the use of high-dose dexamethasone with radiation therapy with improved outcome but significant associated toxicity.[53] They also reported evidence judged to be fair that dexamethasone does not need to be given to asymptomatic ambulatory patients with spinal cord compression receiving x-ray therapy.[54] Although no corresponding evidence is available to support the role of dexamethasone in improving outcome in spinal cord compression caused by solid tumors in pediatric patients, little substantial detrimental effect has been observed with the routine use of dexamethasone in the setting of acute spinal cord compression. Increased rates of infection and delayed wound healing are possible concerns. The use of gastric protectants is advised when administering dexamethasone in this setting and should include H2 blockers and/or proton pump inhibitors. Blood pressure and glucose levels should be monitored, and any increase above age norms should be treated appropriately.

In the case of a child presenting with a high index of suspicion of spinal cord compression caused by tumor and *any* neurologic compromise, rapid administration of dexamethasone at 1 to 2 mg/kg IV to be administered over 30 minutes is suggested. This dose should be administered prior to imaging. If no neurologic symptoms are present, lower oral dosing, 0.25 to 0.5 mg/kg every 6 hours, may be initiated while imaging is arranged. If the child is found to have a spinal lesion and radiation therapy is chosen as the modality for treatment of cord compression, use of moderate-dose dexamethasone is sometimes continued to decrease the effects of radiation-induced swelling and vasogenic edema.

Radiotherapy

Most tumors causing spinal cord compression in the pediatric population will respond to radiotherapy, and thus this modality can often be used emergently to relieve symptoms of spinal cord compression effectively. The benefits of its use include possible rapid response, reasonable tolerance, and avoidance of more invasive procedures. Potential drawbacks include interference with establishing a correct pathologic diagnosis, long-term effects on the spinal column (including stunted growth, cord damage, and scoliosis), thyroid dysfunction, and the risk of secondary malignancies. Additionally, young pediatric patients may require anesthesia for planning and delivery of radiotherapy fractions. For safety and accuracy, adequate imaging, usually through MRI, is required to define the length, depth, and width of the planned treatment field.

Several approaches can be used to deliver a therapeutic treatment dose.[55] Midline lesions, as well as lesions in the lumbar spine, may be treated through a parallel opposed anteroposterior-posteroanterior beam arrangement. A posterior field alone can be used for lesions in the thoracic spine. The cervical spine may be treated with opposed lateral fields in an effort to avoid the oral cavity. Conformal techniques can allow for more precise localization of the radiation therapy to the tumor volume. However, these methods require more elaborate planning and may delay the initiation of therapy. The potential benefit of a more conformal field must be weighed against the additional time and planning required.

Radiotherapy dose and schedule are determined by the pathologic diagnosis, extent of spinal involvement, possible coadministration of chemotherapy, and the patient's clinical situation (e.g., previously ambulatory or nonambulatory, overall life expectancy, likelihood of response to systemic therapy, and previous history of radiation therapy). A dosing range of 18 to 40 Gy can be used. Commonly used schedules include 30 Gy delivered in 10 fractions, 20 Gy given in 5 fractions, or up to 35 to 40 Gy spread over a more protracted course of 3 to 4 weeks. However, 8-Gy single fraction radiotherapy has been successfully used for palliation in patients with a grim prognosis and spinal cord compression, and a recent systematic review suggested that 30 Gy over 10 fractions was a preferred regimen for patients with a good prognosis.[56,57]

The concomitant use of dexamethasone with radiation therapy is often recommended. Dexamethasone is usually begun at a high dose prior to starting radiotherapy, continued at a lesser dose during the procedure, and tapered off after completion. The use of dexamethasone with a taper is thought to decrease some of the edema that can occur as a result of the radiotherapy. Although newer radiation modalities such as Gamma Knife radiosurgery and CyberKnife radiosurgery have been used in adult patients with spinal cord compression, pediatric use of these technologies for spinal cord compression has not been reported to date.[5,58]

Clinical Studies

Although much laudable investigation has been undertaken to address the best choice of initial therapy for children with spinal cord compression, no consensus has been reached to date. The available data are limited by relatively small sample sizes because of the overall rarity of spinal cord compression. Larger series tend to group multiple histologic diagnoses, which may respond differently to the interventions of chemotherapy, radiation, and surgery. Many of the studies also span long intervals and cannot necessarily take into account modernization of practice, improved imaging modalities, and improved therapeutic options.

Pollono and colleagues[36] have reported on a review of 70 pediatric patients with spinal cord compression treated at a single institution from 1984 to 2001; 71% were extradural tumors and 54% were soft tissue sarcomas or neuroblastoma. Figure 68-6 presents the algorithm by which these patients were diagnosed and treated. Patients with paraplegia of less than 96 hours' duration underwent laminectomy, as did patients with primary spinal cord tumor or isolated recurrence of main tumor, progression of symptoms after radiation or chemotherapy, or, if known, a radiation- and chemotherapy-resistant tumor. Surgery was avoided when the prognosis of the primary tumor was poor or risks were thought to outweigh benefits. Of patients with paraplegia, 57% became

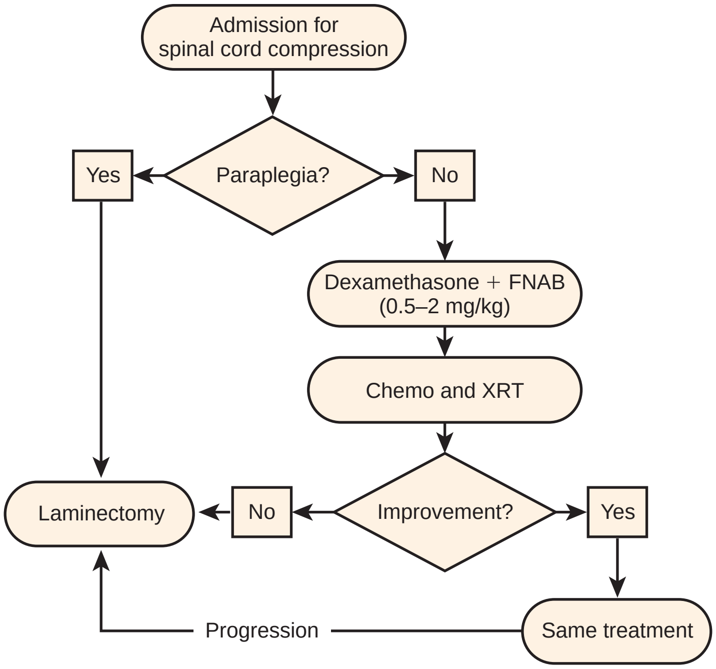

Figure 68-6 Algorithm for diagnosis and treatment of spinal cord compression. With tumor resection, paraplegia of less than 96-hour evolution in patients younger than 1 year and of less than 24 hours in older patients. *Chemo,* Chemotherapy; *FNAB,* fine-needle aspiration biopsy for diagnosis; *XRT,* x-ray therapy. *(Modified from Pollono D, Tomarchia S, Drut R, et al: Spinal cord compression: a review of 70 pediatric patients.* Pediatr Hematol Oncol *20:457–466, 2003.)*

ambulatory after undergoing a laminectomy, whereas only 14% improved after use of chemotherapy and radiation. In patients who presented without paraplegia and received medical treatment without surgery, 87% remained ambulatory. Overall survival was related to the original malignancy. These data suggest that patients with chemotherapy- and radiotherapy-sensitive tumors without evidence of progressive neurologic damage might be treated with chemotherapy and/or radiation therapy but that any indication of neurologic progression is a strong indication for laminectomy without delay.

The question of upfront chemotherapy versus surgery or radiation therapy for spinal cord compression has been most extensively studied in pediatric patients with neuroblastoma, because rapid improvement with initial chemotherapy has been demonstrated. The first reports on the use of chemotherapy as frontline therapy in children presenting with dumbbell neuroblastoma was published in 1984 by Hayes et al.[59] Eleven children with presenting neurologic symptoms were treated; 9 had complete recovery and 2 demonstrated sustained paraplegia. In 1989, Sanderson and coworkers[60] also reported encouraging results of two children with paraplegia and two with paraparesis who both demonstrated full neurologic recovery after treatment with vincristine, cisplatin, etoposide, and cyclophosphamide therapy. Since then, more investigations have been conducted on the use of frontline chemotherapy compared with neurosurgical intervention. Both prospective and retrospective studies have attempted to elucidate whether chemotherapy or surgery is the best initial choice of therapy, but the results yielded have conflicting conclusions. The variability in outcome likely reflects the difficulty of appropriately grouping patients based on initial presenting signs and extent of disease, as well as institutional practice variations and availability of resources.

A series of these studies has been well summarized by De Bernardi and colleagues.[43] Studies from several major international cooperative groups (Italy, Germany, Poland, United Kingdom, and United States) were reviewed. The Italian Cooperative Group for Neuroblastoma has reported a prospective study in which 26 patients with neuroblastoma and spinal cord compression were preferentially given chemotherapy rather than surgery or radiation therapy. Prior to this study, patients followed up between 1979 and 1998 by this group had been analyzed.[61] Retrospective analysis of the earlier patient group showed that radiotherapy, laminectomy, and chemotherapy have comparable ability to improve spinal cord compression. The prospective study also concluded that chemotherapy adequately relieves neurologic symptoms in most patients. Neurologic and orthopedic sequelae were seen in a large number of patients, including those who received chemotherapy only.

In another prospective study carried out by the French Society of Paediatric Oncology, 78 patients with intraspinal extension of neuroblastoma were treated, beginning in 1990.[62] Of these patients, 86% were initially treated with chemotherapy; 63% had a complete neurologic recovery and 21% had a partial neurologic recovery. Also, 13% failed to improve with chemotherapy, the disease of 1 patient progressed, 14% underwent primary surgery, 23% of initially symptomatic patients (10 of 43) had severe neurologic sequelae, 16% had mild sequelae, and 23% were reported to have severe orthopedic sequelae.

One of the largest series contained 83 patients registered for the Pediatric Oncology Group Neuroblastoma Biology Protocol 9047, in which 66 patients received upfront chemotherapy, 23 underwent primary laminectomy, 8 received initial radiotherapy, and 31 underwent initial surgical resection without laminectomy.[63] From this series of retrospectively collected data, it was concluded that patients with neurologic symptoms can be managed without laminectomy and that laminectomy should be reserved for patients who demonstrate progressive neurologic deterioration after initial chemotherapy. The likelihood of neurologic sequelae was found to be inversely related to the length of symptoms prior to initiation of treatment, and more severe sequelae were seen in patients presenting with more severe symptoms. Twenty-nine percent of patients had orthopedic sequelae, and the incidence was significantly lower in patients managed with chemotherapy compared with those who underwent laminectomy.

After a review of multiple studies, the primary conclusion of the neuroblastoma workshop was that a need exists for the creation of an international spinal cord compression registry.[43] The workshop group specified the need to standardize language and criteria to group patients with comparable degrees of neurologic compromise at presentation accurately and to characterize the late effects uniformly. A functional grading system proposed by Gilbert and colleagues[64] was used in some studies to aid in outcome analysis, but it has not been universally adopted (Table 68-2). This grading system notably does not take into account sphincter dysfunction, an important neurologic finding.

It was also concluded that chemotherapy is a reasonable initial approach, but laminectomy should be used for patients who demonstrate progressive neurologic symptoms after presentation or no restoration in the short term.[43] Patients with symptoms occurring within 96 hours of presentation may also be considered candidates for surgical intervention. It was also proposed that radiotherapy may be underused in spinal cord compression caused by neuroblastoma.

Because of the heterogeneity of pediatric malignancies, the findings of the neuroblastoma group cannot automatically be generalized for other types of cancer. Smaller series of outcomes of patients with Ewing sarcoma and intraspinal lesions have also described mixed use of upfront therapies, with variable outcomes. In a report of a series of seven patients with primary Ewing sarcoma of the spine, as well as a review of the literature, Sharafuddin and colleagues[65] noted the importance of the location (sacral or nonsacral) of the presenting lesion in the response to treatment. Differences in response in adult and pediatric patients were also noted. Figure 68-7 shows the algorithm that they proposed for the management of primary Ewing sarcoma of the spine. Initial chemotherapy or limited surgical decompression is recommended for all pediatric patients; surgical intervention is clearly indicated for patients who demonstrate progressive findings with medical treatment.

The rare cases of leukemia and lymphoma that present with spinal cord compression should be treated with initial chemotherapy. Radiotherapy can be considered for some special cases.

TABLE 68-2 Functional Grading Scale of Spinal Cord Compression

Grade	Patient Function
1	Ambulatory, with or without weakness of lower extremities or ataxia
2	Not ambulatory, but able to lift legs against gravity when supine
3	Paraplegic and unable to move legs against gravity

Modified from Lewis DW, Packer RJ, Raney B, et al: Incidence, presentation, and outcome of spinal cord disease in children with systemic cancer. Pediatrics *78:438–443, 1986.*

Late Effects

The long-term consequences of spinal cord compression and its management include neurologic compromise and orthopedic effects, and the choice of initial management heavily takes into account an attempt to minimize those late effects. A number of reports have supported the observation that neurologic sequelae are most related to the degree of presenting neurologic compromise; the more severe the neurologic compromise at presentation, the more likely long-term sequelae will be seen. Other studies have also shown that the duration of time between the development of neurologic symptoms and the initiation of therapy is inversely correlated with the degree of neurologic recovery.[49,63] Although laminectomy may be the most likely method to correct or prevent neurologic sequelae, it is clearly not necessary in all cases of spinal cord compression and carries the greatest risk of orthopedic sequelae. For patients with neuroblastoma in particular, the initial treatment for spinal cord compression did not demonstrate a clear impact on late effect frequency at a median follow-up of 8 years.[66] Orthopedic sequelae include scoliosis, growth impairment, and spinal instability. Orthopedic sequelae are related to the spinal level of the lesion and the age of the patient at treatment. The most severe sequelae are seen in patients with thoracic versus lumbar lesions and age younger than 12 months. Although a wide range of rates of sequelae has been reported, almost all studies have supported the observation of significantly greater orthopedic sequelae in patients who undergo surgery. In a study by Hoover and coworkers,[67] a scoliosis incidence of 67% was found in patients who underwent laminectomy compared with an incidence of 36% in patients who did not undergo laminectomy. Correlation between late effects, including differences in health-related quality of life and initial treatment, remain at the center of investigations into the optimal choice of initial therapy.

and mild to severe pulmonary and neurologic symptoms can accompany the initial finding of hyperleukocytosis or can develop shortly after presentation. Stasis of leukemic cells within blood vessels and migration of blast cells into tissues can lead to the clinical entity of leukostasis, with mortality rates reported as high as 20% to 40%.[68-70] Despite the relative frequency of this true oncologic emergency and several varied therapeutic options, no data-driven management guidelines are available because of overall small numbers of patients, variability of clinical presentation, molecular differences in the underlying disease, and the difficulty of conducting randomized clinical trials with these constraints.

Definition

Hyperleukocytosis is generally accepted as a white blood cell (WBC) count higher than 100×10^9/L, although some studies have included patients with a WBC count higher than 50×10^9/L. It is estimated to occur in 5% to 20% of childhood leukemias and is seen most frequently in infant ALL and T-cell ALL. Hyperleukocytosis is more associated with certain subtypes of ALL and AML and is seen in almost all cases of childhood chronic myelogenous leukemia (Table 28-2). It has long been observed that the occurrence of leukostasis does not correlate directly with degree of hyperleukocytosis. Although hyperleukocytosis is seen more frequently in children with ALL, clinical leukostasis is seen more frequently in children with AML, particularly in M4 and M5 French-American-British subtypes. Clinical symptoms from hyperleukocytosis generally occur at WBC counts higher than 200 to 300×10^9/L in patients with AML and higher than 400 to 500×10^9/L in patients with ALL.[71] However, symptoms of leukostasis have also been observed in patients with WBC counts lower than 100×10^9/L.[69,72,73]

Clinical Presentation

Clinical symptoms of leukostasis are dependent on the system affected. Any small vessels, and therefore any organs, can be at risk. Although pulmonary and neurologic symptoms are most often observed, involvement of many other systems has also been reported. Hyperleukocytosis has been reported to result in leukostasis, causing renal failure, papilledema, dactylitis, priapism or clitorism, acute myocardial infarction, and cardiac failure.[74-76] Histopathologic studies have demonstrated aggregates of blast cells and thrombi leading to occlusion of small vessels in multiple organs of patients with hyperleukocytosis.[77] Corresponding to observed clinical symptoms, postmortem examinations have shown profound infiltration of multiple organs, including brain (including retinal vessels), liver, spleen, adrenals, and pulmonary vasculature, and in the alveoli and connective tissue of the lungs. A striking image of leukemic infiltration of a coronary artery was obtained by Thornton and Levis[75] (Fig. 68-8, Table 68-3).

The observance of the clinical expression of leukostasis and the accompanying related comorbidities has evolved to a description of a leukostasis syndrome, which has been defined as a critical condition with severe metabolic

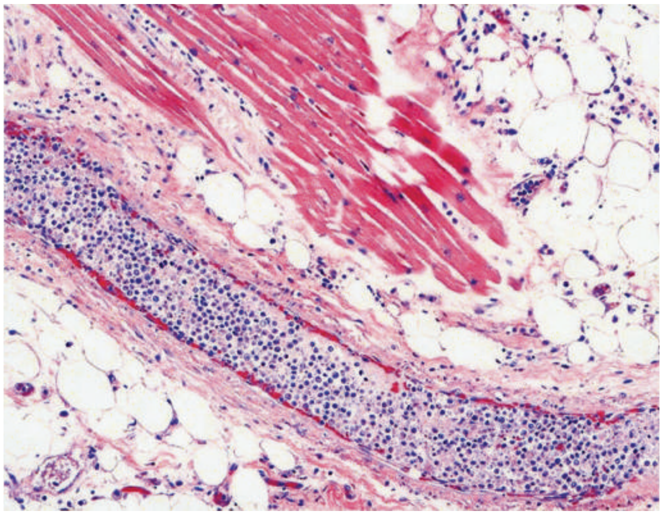

Figure 68-8 Small vessels throughout the body are at risk of occlusion in a patient with hyperleukocytosis. This image shows a coronary artery filled with fms-related tyrosine kinase 3–internal tandem duplication+ (FLT3-ITD+) acute myelogenous leukemia blasts. *(Modified from Thornton KA, Levis M: Images in clinical medicine: FLT3 mutation and acute myelogenous leukemia with leukostasis.* N Engl J Med *357:1639, 2007.)*

abnormalities, tumor lysis syndrome, severe coagulopathy, and multiorgan failure that occurs in patients presenting with hyperleukocytic leukemia.[78,79]

Pathogenesis

The pathogenesis of leukostasis is under continued investigation as researchers have realized the importance and potential clinical relevance of understanding the pathophysiology involved. Increased blood viscosity is often postulated to contribute to the development of leukostasis. At high flow rates (in larger vessels), bulk viscosity of the blood is a function of the deformability of the blood cells and the fraction of blood represented by these cells.[72] The overall viscosity of the blood generally has been found not to increase, even with the marked increase in leukocytic cells, in part because of the corresponding decrease in erythrocrit with increasing leukocrit. In patients with associated moderate to severe anemia, observed leukocrit levels greater than 20% to 25% are needed to demonstrate an objective increase in blood viscosity. Transfusion of red blood cells prior to reduction of the leukocyte count will increase the erythrocrit and can therefore result in hyperviscosity, which can be extremely deleterious to the patient, inducing clinical manifestations of hyperviscosity.

Blood viscosity in the microcirculation can increase because the viscosity is a function of the plasma viscosity and the deformability of the individual cells in the capillaries. Leukemic blasts are larger and less deformable than are erythrocytes or normal leukocytes. Flow in microvessels will slow if the diameter of the poorly deformable blast cell approaches that of the channel. Lymphoblasts range in size from 250 to 350 mm^3 and myeloblasts from 350 to 450 mm^3. It has been suggested that the larger size of myeloblasts compared with lymphoblasts helps account for the greater incidence of intracerebral hemorrhage that has been observed in patients who have AML compared with those who have ALL.[71] Histopathologic studies have revealed leukocyte thrombi and aggregates in the cerebral vasculature of patients with AML.

Appreciation of the role of adhesion molecules and the endothelial lining of the blood vessels is increasing. Laboratory observations have shown that expression of intracellular adhesion molecule–1, vascular cell adhesion molecule–1, and E-selectin can be induced in endothelial cells exposed to supernatants of blast cell cultures.[80] This effect was regulated by blast cell production of tumor necrosis factor-α and interleukin-1β. It is suggested that through this self-perpetuating interaction, leukemic blasts can promote their own adhesion to inactivated vascular endothelium. Alternate mechanisms of leukostasis have also been proposed and are being investigated, including molecular interactions directly between leukemic blast cells, leading to clumping and intravascular aggregates.

The molecular origin and subsequent cell phenotype is likely important to the role in developing leukostasis. The expression of CD56 neural cell adhesion molecule on leukemic blasts in a study of adult patients with AML was correlated with the development of severe clinical leukostatic syndrome.[78] In another study of adult patients with acute promyelocytic leukemia (APL, or level M3 AML), expression of CD13 (aminopeptidase N), a cell surface enzyme previously linked to tumor cell invasion, was highly associated with elevated leukocyte count and the development of all-*trans*-retinoic acid syndrome.[2] Further study in these intriguing areas of research is needed to confirm these findings and to test the applicability to pediatric patients. It is hoped that a better understanding of the underlying pathophysiology will lead to methods for early detection of patients at highest risk for severe leukostasis and eventually provide pharmacologic targets for disruption of the interaction of adhesion molecules, resulting in clinical improvements.

TABLE 68-3 Factors Associated With Occurrence of Hyperleukocytic Leukemias in Childhood

Acute Lymphoblastic Leukemia	Acute Myelogenous Leukemia
Age <1 year	Age <1 year

*FLT3 internal tandem duplication, shown in young adults.[74]

Clinical Presentation

Clinical manifestations of hyperleukocytosis and leukostasis can be myriad. Many patients with hyperleukocytosis are relatively asymptomatic. Clinical leukostasis can present subtly and evolve rapidly. Most commonly, pulmonary symptoms are observed. Tachypnea, oxygen desaturation, and dyspnea can occur and can progress rapidly to acute respiratory disease syndrome and respiratory failure. Neurologic symptoms can include headache, tinnitus, ataxia, behavioral changes, seizures, and stroke. Hemorrhagic stroke is a highly morbid complication of hyperleukocytosis and is seen most often in the microgranular variant of APL (level M3v AML). Often these patients have associated disseminated intravascular coagulation and thrombocytopenia, increasing their risk for hemorrhage.

Symptoms can rapidly worsen after initiation of therapy. It has been postulated that this phenomenon may be caused by release of intracellular components of blast cells after lysis, including enzymes that can lead to injury in surrounding tissue, such as alveolar damage and interstitial edema.[81] When using modern pediatric AML protocols for treatment and supportive care, early mortality in patients with AML who have hyperleukocytosis is very low, but hyperleukocytosis continues to be associated with inferior disease outcomes.[82,83] Additionally, Fong and coworkers[84] described unique anesthesia-related considerations for children with hyperleukocytosis and recommend close observation postoperatively for leukostasis-related pulmonary and neurologic events.

Authors of a number of studies have looked at the factors associated with more severe clinical events in patients with hyperleukocytic leukemias, with mixed conclusions. A clinical grading system has been proposed by Novotny and colleagues[79] (Table 68-4). The grading system groups patients into four categories: not present (0), possible (1), probable (2), and highly probable (3). The grading is based on the assumption that the severity of presenting symptoms may indicate the probability of leukostasis, provided another cause for the symptoms is not found. This assumption is supported by the knowledge that patients with respiratory distress or severe neurologic symptoms have a much increased mortality rate.[85] The investigators used this clinical scoring system in conjunction with initial flow cytometry data to show that the detection of CD56 expression at baseline in patients with AML level M4 and M5 disease may identify patients at highest risk for fatal leukostasis. This approach has clear clinical relevance but requires further validation prior to clinical application.

Treatment

Definitive treatment for hyperleukocytosis is the initiation of appropriate induction chemotherapy as soon as a diagnosis is established. Previously, for many years the initiation of IV hydration, urinary alkalinization, and allopurinol was the clinical standard for the immediate initial treatment of hyperleukocytic acute leukemias. In 1995, Basade et al.[86] reported an 81.5% reduction in WBC count within a median of 36 hours in a cohort of pediatric patients who had ALL with the use of IV hydration, urinary alkalinization, and allopurinol. No treatment-related complications occurred in their patient cohort. Although studies have not yet been published, the availability of urate oxalate is likely to modify this practice, because many of these patients clearly meet criteria for high risk of TLS. Early therapy with urate oxalate has the potential to decrease the risk for TLS markedly in patients who have acute hyperleukocytic leukemias, which could decrease the number of patients in whom leukostasis syndrome develops, thereby positively affecting overall morbidity and mortality.

TABLE 68-4 Grading of Symptoms in Hyperleukocytic Leukemia*

Group	Probability of Leukostasis Syndrome	Severity of Symptoms	Pulmonary Symptoms	Neurologic Symptoms	Other Organ Systems
0	Not present	No limitations	No symptoms and no limitations in ordinary activities	No neurologic symptoms	No symptoms
1	Possible	Slight limitations	Mild symptoms and slight limitation during ordinary activity, comfortable at rest	Mild tinnitus, headache, dizziness	Moderate fatigue
2	Probable	Marked limitations	Marked limitation in activity because of symptoms, even during less than ordinary activity, comfortable only at rest	Slight visual disturbances, severe tinnitus, headache, dizziness	Severe fatigue
3	Highly probable	Severe limitations	Dyspnea at rest, oxygen or respirator required	Severe visual disturbances (acute inability to read), confusion, delirium, somnolence, intracranial hemorrhage	Myocardial infarction, priapism, ischemic necrosis

Modified from Novotny JR, Muller-Beissenhirtz H, Herget-Rosenthal S, et al: Grading of symptoms in hyperleukocytic leukaemia: a clinical model for the role of different blast types and promyelocytes in the development of leukostasis syndrome. Eur J Haematol *74:501–510, 2005.*

*Probability of leukostasis deduced from the severity of symptoms attributable to leukostasis (no other obvious cause).

Additional measures to reduce the elevated WBC count and associated morbidities have been studied. Cranial radiation has been proposed to decrease the chance of intracerebral hemorrhage. Based on a study of adult patients with AML and a WBC count higher than 200 × 10^9/L, Wiernik and Serpick[87] have proposed the prophylactic use of 400 to 600 cGy of cranial radiotherapy to prevent intracranial hemorrhage. Several small series that used emergency cranial radiotherapy in pediatric patients with ALL and hyperleukocytosis were also reported, with a low incidence of intracranial hemorrhage.[88] However, subsequent experience has not consistently shown a beneficial effect of prophylactic cranial radiotherapy. Additionally, concerns exist about acute and chronic neuropsychiatric complications associated with cranial radiotherapy in pediatric patients, and thus it is rarely used for this indication in current practice.[89-91]

The use of low-dose prednisone as initial treatment for patients with ALL and hyperleukocytosis has been proposed, with the rationale of inducing a gradual blast cell lysis in an attempt to decrease the severity of metabolic derangements. Along with several other interventions, the use of low-dose prednisone was reviewed in a group of 124 patients with newly diagnosed ALL and a WBC count higher than 200 × 10^9/L who were followed up by the Children's Cancer Study Group from 1981 to 1983.[91] All patients received IV hydration, urinary alkalinization, and allopurinol. Some patients received additional measures (e.g., low-dose prednisone, cranial radiation, exchange transfusion, and leukapheresis) in an attempt to decrease complications. It was concluded that pretreatment with low-dose prednisone does not correlate with fewer electrolyte abnormalities. However, many of the patients in this study received more than one additional treatment, complicating the analysis in this relatively small group of patients.

Leukapheresis and exchange transfusion have both been shown to be effective in reducing the total WBC and blast count. Patients weighing less than 12 kg usually are unable to undergo leukapheresis but may safely undergo exchange transfusion. Studies in pediatric patients have shown a mean reduction of 50% to 60% in WBC with exchange transfusion and leukapheresis.[90,92] However, the rate of WBC clearance with leukapheresis is inconsistent, and the overall benefit of this cytoreduction is unclear.[93]

In patients with ALL, the use of leukapheresis may decrease the risk of severe TLS. Patients with ALL and hyperleukocytosis in the Children's Cancer Study Group cohort who received leukapheresis or exchange transfusion appeared to show some benefit of the procedures, with a lower incidence of severe electrolyte abnormalities and renal dysfunction.[91] The same conclusion was reached by Bunin and Pui[71] in a series of 161 patients with ALL and hyperleukocytosis.

In the three largest studies in patients with AML that examined the role of leukapheresis, differing conclusions were reached. In a group of 22 patients with newly diagnosed AML (ages 12 to 74 years), it was found that decreasing the total WBC count through leukapheresis by at least 30% correlates with improved outcome in those patients.[94] In contrast, in a study by Porcu and colleagues,[85] 48 patients ages 8 to 79 years who had AML or chronic myelogenous leukemia and were in blast crisis underwent immediate cytoreduction with leukapheresis, and no correlation was found between the degree of cytoreduction and early mortality rate. In the largest study, Giles and coworkers[95] reviewed outcomes of 146 patients (ages 16 to 86 years) with AML, 71 of whom underwent leukapheresis. An association with decreased early mortality rate was found, but no improvement occurred in the overall survival rate.

The use of leukapheresis in patients with APL is greatly discouraged because increased rates of mortality have been observed in these patients, which are largely caused by the increased incidence of hemorrhage. Vahdat and colleagues[2] reported fatal or near-fatal hemorrhage in 9 of 11 patients with APL who underwent leukapheresis.

Hydroxyurea is known to be effective in reducing overall WBC and blast counts.[96] At the American Society of Hematology 2006 Annual Meeting, preliminary results of a randomized study on the use of hydroxyurea versus leukapheresis in patients with AML were presented, with equivalent outcome noted at 8 and 28 days and no difference in death rate.[97]

The possible benefits from a rapid reduction in WBC and blast count that can be achieved with leukapheresis or exchange transfusion need to be weighed against the risks of these procedures, which include obtaining adequate venous access and anticoagulation. The decision to initiate leukapheresis must also take into account the time to arrange these procedures, including mobilization of specialized blood bank personnel and possible transfer to tertiary centers where such specialized procedures are available. Institution of these procedures can be particularly deleterious if they delay initiation of definitive chemotherapy treatments. With increased use of urate oxalate, the benefit of leukapheresis in patients with ALL may need to be reassessed.

Conclusions

Acute leukemias presenting with hyperleukocytosis pose immediate clinical challenges to the treating pediatric oncologist and must be addressed rapidly and appropriately. Although many components of treatment of hyperleukocytosis are generally accepted, much ambiguity still exists about the appropriateness of many possible interventions. Although further study is appropriate, carrying out such studies poses many challenges. Box 68-2 groups treatment guidelines into those that have been shown to be clearly beneficial, those that have been shown to be harmful, and those of less certain benefit. It is hoped that translational research into the underlying pathophysiology of the leukostasis syndrome will lead to novel therapeutic modalities and pharmacologic interventions.

TUMOR LYSIS SYNDROME

TLS is the most commonly encountered pediatric oncologic emergency. Diagnosis and treatment strategies have evolved during the past decade with the development of new drug therapy. Morbidity and mortality have improved as the entity is now recognized and treated earlier in

Box 68-2 **Clinical Guidelines for Patients With White Blood Cell Count Greater Than 50×10^9 and Diagnosis of Acute Leukemia**

RECOMMENDED FOR ALL PATIENTS WITH HYPERLEUKOCYTOSIS

- Institution of appropriate chemotherapy as soon as a diagnosis is made
- Careful clinical observation, neurologic examination, frequent laboratory evaluation per tumor lysis protocol, evaluation of renal function, chest radiograph, and oxygen saturation monitoring with supplemental oxygen as needed
- Treatment for TLS with IVF, alkalinization, and allopurinol OR rasburicase and no alkalinization; strong bias toward use of rasburicase if any parameters are met for high risk of TLS-increased uric acid, creatinine, LDH, potassium (see section on TLS)
- Correction of coagulopathy as appropriate with cryoprecipitate, FFP, vitamin K; special consideration of disseminated intravascular coagulation and risk of intracerebral hemorrhage in M4 or M5 level AML, and even greater risk in level M3v APL
- Platelet transfusion for platelet count <25 K or any clinical bleeding

RECOMMENDED IN SOME CLINICAL CIRCUMSTANCES

- Consider exchange transfusion or leukapheresis in patients with ALL and WBC >300-500 × 10^9, or AML and WBC >100-200 × 10^9, particularly if any pulmonary or neurologic symptoms exist
- Consider low-dose prednisone reduction phase prior to induction chemotherapy in patients with ALL and WBC >300-500 × 10^9 (may decrease chance of TLS)

CONTRAINDICATED

- Avoid leukapheresis in patients with APL (substantially increases the risk of intracerebral hemorrhage)
- Avoid use of diuretics or transfusion of PRBC in patients with ALL and WBC >300-500 × 10^9, or AML and WBC >100-200 × 10^9 (confers increased risk of hyperviscosity and clinical leukostasis)

presentation. New therapeutic interventions have become available and are more widely used.

Overview

After the incorporation of cytotoxic chemotherapy into the treatment of hematologic malignancies and solid tumors, recurrent observations were made of severe metabolic abnormalities associated with the onset of therapy.[98,99] The consistent occurrence of these metabolic and electrolyte imbalances, particularly in the setting of lymphoma and leukemia, eventually became recognized as TLS. TLS describes the metabolic derangements that occur as a result of spontaneous or treatment-related breakdown of tumor cells. The release of intracellular contents from the tumor cells into the bloodstream leads to the characteristic triad of hyperuricemia, hyperkalemia, and hyperphosphatemia. TLS is most commonly associated with initiation of therapy for cancers with massive tumor burden or high proliferative rates, such as ALL and Burkitt lymphoma. Predictors of TLS include the presence of bulky disease, adenopathy, hepatosplenomegaly, and a high leukocyte count. Additional risk factors for the development of severe TLS include increased lactate dehydrogenase (LDH), uric acid, creatinine, and decreased urine output.[76,100,101] TLS can result in high morbidity and mortality, with possible rapid progression to multiorgan failure, and thus the prompt identification of patients at risk for this oncologic emergency and the institution of preventive measures are critical. Although the risk of developing TLS is highest at 12 to 72 hours after the initiation of chemotherapy, symptoms can also precede the initiation of therapy or occur as many as 7 days later. The main principles of TLS prevention and treatment include hydration and diuresis, careful monitoring of electrolyte abnormalities, and management of hyperuricemia. In this section, we will discuss the pathophysiology, incidence, and recent advances in the management of TLS.

Pathophysiology

Although TLS can occur spontaneously prior to the administration of chemotherapy, it is most commonly observed after the initiation of therapy. In tumors with a high proliferative rate, large tumor burden, and high chemosensitivity, the exposure of the tumor cells to cytotoxic chemotherapy leads to massive cell lysis, with the release of intracellular anions, cations, and breakdown products of nucleic acids and proteins into the bloodstream. This rapid efflux of intracellular contents can exceed the renal capacity for clearance and consequently can lead to the metabolic derangements and electrolyte imbalances observed in TLS. Hyperuricemia is the most common finding in TLS; it results from the release of intracellular nucleic acids and the subsequent catabolism of the purine nucleotides, adenosine and guanosine. Uric acid, the final product of both endogenous and dietary purine nucleotide catabolism, is normally generated in the liver by oxidation of xanthine to uric acid by xanthine oxidase (Fig. 68-9). Uric acid is a weak acid, with a pK_a of 5.4 to 5.7. At normal concentrations and at physiologic pH, 98% of uric acid is in the ionized form as urate, which is soluble in urine.[102] However, when uric acid is present in high concentrations in acidic urine, it can crystallize in the renal parenchyma, distal tubules, and collecting ducts, leading to intraluminal tubular obstruction and oliguria.

Hyperkalemia poses the greatest immediate threat of mortality because the rapid rise in serum potassium can result in severe arrhythmia and death. This life-threatening consequence of TLS is caused in part by the kidney's inability to excrete the massive quantities of intracellular potassium released from dying tumor cells. The kidney's inability to handle the excessive load of potassium can be amplified by renal dysfunction caused by precipitants such as uric acid. Hyperkalemia in the setting of TLS can be further exacerbated by concurrent metabolic acidosis or iatrogenic administration of potassium with IV fluids.

Hyperphosphatemia results from the rapid release of intracellular phosphorus from tumor cells, which can contain three to four times the amount of phosphorus in normal cells.[3,103] The development of hyperphosphatemia can also worsen in the setting of concurrent acute renal insufficiency as a result of uric acid precipitation. In TLS, the renal tubular capacity to reabsorb phosphorus can be

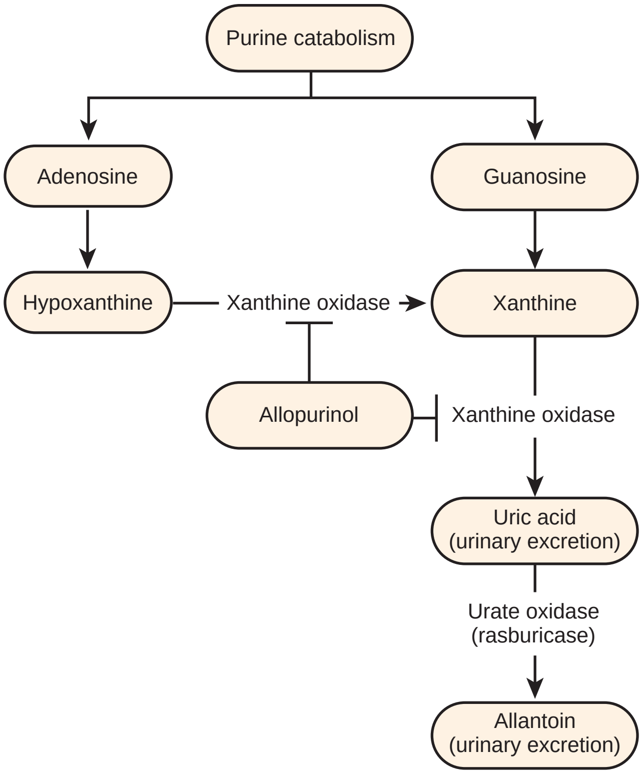

Figure 68-9 Pathophysiology of hyperuricemia in tumor lysis syndrome. Uric acid is a breakdown product of purine nucleotide catabolism. The current pharmacologic strategies for the management of hyperuricemia are allopurinol and rasburicase.

exceeded and lead to hyperphosphaturia. A cyclic process commences, in which the acute hyperphosphatemia and hyperphosphaturia can then lead to acute nephrocalcinosis and renal failure via precipitation of calcium phosphate crystals, further impairing the renal tubular reabsorption of phosphorus. The normal calcium × phosphorus product ranges between 30 and 55 mg^2/dL^2. When this product exceeds 70 mg^2/dL^2, the risk of calcium phosphate deposition in the kidney and other tissues is significant.[104] Metastatic calcification caused by calcium phosphate crystals in other soft tissues is rarely seen in TLS but has been described.[105] In addition, the precipitation of calcium phosphate can lead secondarily to asymptomatic or symptomatic hypocalcemia.

Incidence

The highest incidence of TLS occurs in ALL and high-grade NHL. A retrospective study of 102 patients with high-grade NHL found the incidence of TLS to be 42% based on laboratory evidence, although only 6% of the patients had clinically significant TLS.[106] Similarly, a pan-European retrospective chart review has reported TLS in 5.2% and 6.1% of patients with ALL and NHL, respectively.[107] This study also demonstrated a high incidence of mortality in patients with clinical TLS. Of the patients with TLS in this study, 17.5% died from TLS-related causes.

The incidence of TLS appears to be similar in the pediatric population. A retrospective study of 1192 pediatric patients with any form of NHL identified 63 patients (5.3%) with clinically significant TLS.[108] Among these 63 patients, two patients (3.2%) died within 48 hours of therapy because of electrolyte imbalances. However, another retrospective pediatric study has indicated that the incidence of TLS is significantly higher in patients with B-cell ALL or Burkitt lymphoma stage III or IV, with LDH greater than or equal to 500 units/L. Of the 218 patients who met these criteria initially (prior to the prophylactic use of urate oxidase), TLS developed in 35 (16.1%), and 20 (9.2%) became anuric.[109]

Other hematologic malignancies that have been less commonly associated with TLS include AML, chronic lymphocytic leukemia, and multiple myeloma. Only isolated case reports of TLS have been described in other hematologic malignancies, such as chronic myeloid leukemia in blast crisis, myeloproliferative disorders, and Hodgkin disease. TLS is also uncommon in solid tumors, which generally have a longer doubling time and a slow response to chemotherapy in comparison with lymphoproliferative malignancies. However, TLS can be seen in solid tumors that are highly chemosensitive or that have a high tumor burden, as in bulky, metastatic disease or in tumors that present with renal compromise. In the context of newly diagnosed solid tumors, renal compromise may occur from mass effect and compression. A literature review has identified 45 reported cases of TLS in solid tumors from 1977 to 2002.[110] Most of these cases occurred in tumors with a high response rate to cytotoxic therapy, such as small cell lung carcinoma, germ cell tumors, and breast carcinoma. Among the 45 reported cases, 16 patients (35.5%) died as a result of TLS. Risk factors for the development of TLS in persons with solid tumors were similar to those in persons with hematologic malignancies—increased LDH, hyperuricemia, and pretreatment renal impairment. However, the mortality rate caused by complications from TLS in these patients with solid tumors was higher than reported mortality rates in patients with hematologic malignancies. This finding may be the result of better implementation of prophylactic measures in patients with hematologic malignancies resulting from a greater awareness of TLS in this population.

Diagnosis

TLS should be anticipated in all new-onset oncology patients, with the highest concern for those presenting with a large tumor burden and concurrent laboratory abnormalities. Although many general criteria exist for TLS, a uniform, widely accepted definition for TLS is lacking. A standardized definition would enable a more exact determination of TLS incidence and would also improve the ability to evaluate and compare therapies for the prevention of TLS. Two classification systems for TLS have been developed and are variably followed, the Hande-Garrow system (Boxes 68-3 and 68-4) in 1993 and the Cairo-Bishop system in 2004. The Hande-Garrow classification system makes a distinction between laboratory and clinical TLS based on the observation that only a fraction of patients with TLS according to laboratory criteria experience clinically significant TLS.[106]

Box 68-3 **Hande-Garrow Definition of Laboratory Tumor Lysis Syndrome***

A 25% increase over pretreatment values in serum phosphate, potassium, uric acid, or urea nitrogen.
or
A 25% decline in serum calcium.

*Any two of the metabolic changes must occur within 4 days of treatment.

Box 68-4 **Hande-Garrow Definition of Clinical Tumor Lysis Syndrome***

Rise in serum creatinine >2.5 mg/dL.
Serum potassium level >6.0 mmol/L.
Decline in serum calcium to <6 mg/dL.
Development of life-threatening arrhythmia or death.

*Clinical tumor lysis syndrome is defined as the presence of laboratory tumor lysis syndrome and any one of the criteria in this box.

Laboratory TLS (LTLS) designates patients who have laboratory evidence of metabolic changes as a result of tumor cell breakdown but who do not require any therapeutic intervention. Patients with any of the following metabolic changes occurring within the first 4 days of treatment are defined as having LTLS: (1) a 25% increase compared with pretreatment values in serum phosphate, potassium, uric acid, or urea nitrogen levels or (2) a 25% decline in the serum calcium level. Clinical TLS (CTLS) is designated in any patient with LTLS who also experiences one of the following: (1) a rise in the serum creatinine level greater than 2.5 mg/dL; (2) a serum potassium level greater than 6.0 mmol/L; (3) a decline in the serum calcium level to less than 6 mg/dL; (4) the development of a life-threatening arrhythmia; or sudden death. In practice, this classification system has several limitations. First, in requiring a 25% increase in the baseline laboratory value, the definition of LTLS does not account for patients who have preexisting abnormal laboratory values at presentation. In addition, the definition requires that the laboratory changes occur within 4 days of starting therapy, which excludes patients with clinical evidence of TLS at presentation or patients in whom TLS develops beyond 4 days of therapy. Additionally, any symptomatic hypocalcemia should alone constitute CTLS.[111]

The Cairo-Bishop classification system is a modified version of the Hande-Garrow system that aims to be more clinically relevant (Table 68-5).[112] For example, the definition of LTLS has been extended to include a window of 3 days before and 7 days after the initiation of therapy. Similar to the Hande-Garrow system, the definition of CTLS requires the presence of LTLS, plus one or more of the three most significant clinical complications associated with TLS: renal insufficiency, cardiac arrhythmias or sudden death, and seizures. Cairo and Bishop also introduced a grading system for TLS that incorporates their definitions of no TLS, LTLS, and CTLS. This grading system was evaluated as part of a Children's Oncology Group study of chemoimmunotherapy and rasburicase in patients with newly diagnosed NHL (trial ANHL01P1). One of the specific aims of this study was to determine the incidences of TLS, consequent renal complications, and the requirement for assisted renal support (e.g., dialysis or hemofiltration) during the reduction phase and first induction phase of therapy in children with newly diagnosed advanced-stage leukemia or lymphoma. It was found that the rasburicase was safe and well tolerated. Increased initial LDH was correlated with increased uric acid level, increased incidence of TLS, and lower glomerular filtration rate. Patients treated with rasburicase have only a 9% and 5% incidence of LTLS and CTLS, respectively. Importantly, a significant improvement in estimated glomerular filtration rate from day 0 to day 7 was found in patients after administration of rasburicase, and only 3% of patients required new-onset renal-assisted support after administration of rasburicase.[113]

Building on the Cairo-Bishop and Hande-Garrow definitions of LTLS and CTLS, an algorithm for the assessment

TABLE 68-5 Cairo-Bishop Grading Classification of Tumor Lysis Syndrome

Grade	LTLS	Creatinine Level	Cardiac Arrhythmia	Seizure
0	–	≤1.5 × ULN	None	None
I	+	1.5 × ULN	Intervention not indicated	None
II	+	>1.5-3.0 × ULN	Nonurgent medical intervention indicated	One brief generalized seizure, seizure(s) well controlled by anticonvulsants, infrequent focal motor seizures not interfering with ADLs
III	+	>3.0-6.0 × ULN	Symptomatic and incompletely controlled medically or controlled with device (e.g., defibrillator)	Seizure in which consciousness is altered, poorly controlled seizure disorder, breakthrough generalized seizures despite medical intervention
IV	+	>6.0 × ULN	Life-threatening (e.g., arrhythmia associated with CHF, hypotension, syncope, shock)	Seizures of any type that are prolonged, repetitive, or difficult to control (e.g., status epilepticus and intractable epilepsy)
V	+	Death	Death	Death

and initial management of TLS was proposed by Howard and colleagues (Fig. 68-10).[111] It is important to note that this guide is intended for a patient at the time of presentation, however; subsequent care and interventions should reflect the clinical course, expected or not, of the patient. When distinguishing the best classification group for a patient is difficult, it is always advisable to provide treatment as if the patient is in the higher risk group.

Clinical Manifestations and Treatment

Clinical manifestations of acute TLS include nausea, anorexia, cardiac arrhythmias, seizures, muscle cramps, tetany, oliguria or anuria, and alterations in consciousness. These symptoms primarily result from the electrolyte disturbances seen in TLS (described earlier). The most important objectives for the successful management of acute TLS are the prompt identification of patients at high risk for the development of TLS and aggressive institution of appropriate prophylactic measures to prevent and/or reduce the severity of the clinical manifestations of acute TLS (Box 68-5). Initial studies that can predict TLS and guide preventive management include serum electrolyte, calcium, phosphate, blood urea nitrogen, creatinine, and uric acid levels. This panel of laboratory assessments should be performed promptly for any patient presenting with new diagnosis of malignancy. The main preventive measures are hydration and optimization of urine output, along with prevention of uric acid synthesis by allopurinol or rasburicase. In addition to the specific treatment recommendations discussed later, patients at risk for TLS should be carefully observed with use of cardiovascular and respiratory monitors. Frequent vital signs and strict fluid assessments including intake and output should be recorded. Laboratory tests should be performed at a minimum every 6 to 8 hours initially, and the results should be evaluated immediately (see Box 68-5).

Box 68-5 **Management of Patients at Risk for Tumor Lysis Syndrome**

HYDRATION

Dextrose 5% in half-normal saline solution (without potassium)
Recommended rate: two times maintenance (125 mL/m^2/hour)

ALKALINIZATION

Routine alkalinization is not recommended; use with allopurinol when the primary concern is uric acid level and when use of rasburicase is contradicted or it is not available
Modify $NaHCO_3$ as needed to maintain urine pH at 7.0 to 8.0
Stop $NaHCO_3$ if the serum bicarbonate level is ≥30 mEq/L and/or urine pH is >8.0 or if hyperphosphatemia develops

DIURESIS

Maintain urine output at >100 mL/m^2/hour and urine specific gravity at <1.010
Consider furosemide (0.5 to 1.0 mg/kg) or mannitol (0.5 g/kg) for low urine output in the absence of hypovolemia

URIC ACID REDUCTION

Consider the role of allopurinol or urate oxidase (rasburicase), based on assessment of the potential of TLS, initial uric acid and phosphate level, drug availability, and G6PD status:
- Options: Allopurinol: by mouth, 100 mg/m^2 three times daily, or 10 mg/kg/day divided in three doses
- Rasburicase: IV, 0.2 mg/kg once daily for up to 5 days
  - Indicated when serum creatinine is >1.5 times the upper limit or normal, or when uric acid is >7.0 mg/dL; consider at lower levels if the patient is assessed to be at high risk of TLS or if hyperphosphatemia exists
  - Contraindicated in patients with G6PD deficiency
  - Discontinue allopurinol if using rasburicase
  - No bicarbonate necessary in IV fluid

METABOLIC ABNORMALITIES

Monitor serum electrolytes every 4 to 8 hours

HYPERKALEMIA

Moderate (≥6.0 mmol/L)
- Avoid IV and oral potassium
- Electrocardiogram and cardiorespiratory monitor
- Kayexalate (1 g/kg orally with 25% sorbitol every 6 hours)

Severe (>7.0 mmol/L and/or symptomatic)—same as for moderate hyperkalemia, plus:
- Albuterol nebulization treatment
- Insulin (0.1 units/kg) with concurrent 25% dextrose (2 mL/kg)
- Calcium gluconate (100 to 200 mg/kg)
- Dialysis

HYPERPHOSPHATEMIA

Moderate (≥5.0 mg/dL)—aluminum hydroxide 50-150 mg/kg/24 hours in divided doses every 4-6 hours
Severe (with symptomatic hypocalcemia)—dialysis, CVVH, and CVAH

HYPOCALCEMIA

Asymptomatic—no therapy
Symptomatic—calcium gluconate (50 to 100 mg/kg/dose)

Fluids and Alkalinization

Unless the patient presents with signs of acute renal failure or oliguria, aggressive hydration is the most important intervention. IV fluids should be administered at a rate of 3000 mL/m^2/day, and brisk urine output should be maintained (more than 100 mL/m^2/hour), with a urine specific gravity goal of less than or equal to 1.010. This increased hydration and increase in urine flow promotes urinary excretion of uric acid and phosphate by enhancing renal blood flow and glomerular filtration. Potassium, calcium, and phosphate should not be added to initial hydration fluids to avoid iatrogenic aggravation of hyperkalemia, hyperphosphatemia, or calcium phosphate precipitation. If urine output remains low despite aggressive hydration (usually caused by third spacing), diuretics may be used as long as there is no evidence of acute obstructive uropathy and/or hypovolemia. Commonly used diuretics are mannitol (0.5 g/kg) or furosemide (0.5 to 1.0 mg/kg).

Urine alkalinization remains controversial, although historically it has been a general recommendation for the prevention and treatment of TLS. An alkaline urine (urine pH ≥6.5) promotes urinary excretion of urate, with maximal solubility of urate occurring at a pH of 7.5.[114] However, the solubility of its precursors, xanthine and hypoxanthine, significantly decreases at a pH greater than or equal to 6.5. Thus excessive systemic and urinary alkalinization may lead to metabolic alkalosis and obstructive uropathies from xanthine and hypoxanthine crystallization. In addition, alkalinization of urine favors precipitation of calcium phosphate crystals in the renal tubules, a risk that can be further exacerbated by concomitant hyperphosphatemia. Metabolic alkalosis can also worsen the neurologic manifestations of hypocalcemia. Thus sodium bicarbonate should be used judiciously, with checks of urine pH with every void. If rasburicase is used, urine should not be alkalinized. If allopurinol is being used, alkalinization can be considered, but its use should be discontinued once serum uric acid normalizes, the dose should be decreased for urine pH greater than 8, and it must be discontinued if hyperphosphatemia develops.

Hyperkalemia

In the setting of TLS, hyperkalemia results from the massive efflux of intracellular potassium from dying tumor cells. Clinical manifestations include neuromuscular signs and symptoms such as muscle weakness, cramps, and paresthesias. Cardiac manifestations may include peaked T waves on an electrocardiogram, malignant arrhythmias, and conduction disturbances. Hyperkalemia is usually defined by a serum potassium level greater than or equal to 6.0 mmol/L. However, in the clinical setting of ongoing tumor lysis, a serum potassium level greater than 5.0 mmol/L and/or a trend of increasing values also merit intervention. Treatment of hyperkalemia is based on three approaches: driving extracellular potassium into cells, removing excess potassium from the body, and antagonizing the membrane effects of potassium. In asymptomatic patients, it is reasonable to begin simply with increased hydration with alkalinized fluids and diuresis with furosemide. The treatment of choice after alkalinization and optimization of urine output often is a potassium-binding cation exchange resin, such as sodium polystyrene sulfonate (1 g/kg/dose orally every 6 hours). This resin can also be given as a retention enema, but oral administration is more efficacious. Each gram of resin may bind as much as 1 mEq of potassium and release 1 to 2 mEq of sodium. For symptomatic patients, more rapid-acting treatments are required, such as insulin and β_2-adrenergic agonists, which drive potassium into cells by enhancing the activity of the Na+,K+ adenosine triphosphatase pump in skeletal muscle. Insulin is usually given as a bolus (0.1 unit/kg) with concurrent glucose infusion (25% dextrose, 2 mL/kg). Commonly used β_2-adrenergic agonists in the treatment of hyperkalemia are albuterol nebulizer treatments and IV epinephrine. Interventions commonly used in the fluid management of TLS, such as alkalinization and diuretics, can also help in the reduction of serum potassium. The increase in systemic pH with sodium bicarbonate results in hydrogen ion release from the cells as part of the buffering reaction; this change results in the movement of potassium into the cells to maintain electroneutrality. Loop and thiazide diuretics can lead to a transient lowering of serum potassium. Calcium directly antagonizes the inactivation of sodium channels and decreased membrane excitability caused by hyperkalemia. Thus calcium gluconate (100 to 200 mg/kg) can be given to stabilize myocardial conduction in cases of severe hyperkalemia or the presence of electrocardiographic abnormalities. Because concomitant hyperphosphatemia and alkalinization in the setting of TLS can increase the risk of calcium phosphate or calcium carbonate precipitation, calcium infusions should be given only when absolutely necessary. Finally, dialysis can be used if the conservative measures listed earlier are ineffective or if the hyperkalemia is severe.

Hyperphosphatemia

Clinical manifestations of severe hyperphosphatemia include nausea, vomiting, diarrhea, lethargy, and seizures. Physiologically, hyperphosphatemia increases the risk of tissue precipitation of calcium phosphate, which can subsequently lead to intrarenal calcification, acute obstructive uropathy, or symptomatic hypocalcemia. Hyperphosphatemia is usually defined by a phosphorus level greater than or equal to 5.0 mg/dL in children. Initial treatment for significant hyperphosphatemia consists of administration of oral forms of phosphate binders, such as aluminum hydroxide at a dosage of 50 to 150 mg/kg/day divided into equal doses every 6 hours. Acute severe hyperphosphatemia with symptomatic hypocalcemia can be life-threatening. However, given the real risk of worsening precipitation of calcium phosphate complexes, patients with hyperphosphatemia should not receive calcium infusions unless they have clinical symptoms of hypocalcemia. Patients with impaired renal function may require more aggressive therapy, such as peritoneal dialysis, hemodialysis, or continuous venovenous hemofiltration. Of these modalities, hemodialysis appears to be the most efficacious at clearing phosphorus.[115]

Hypocalcemia

During acute TLS, hypocalcemia commonly occurs because of precipitation of calcium phosphate, which in turn is a consequence of hyperphosphatemia. Many patients experience symptoms when their serum ionized calcium concentration is less than or equal to 0.7 mmol/L or their serum total calcium concentration is less than or equal to 7 mg/dL. Muscular manifestations of hypocalcemia include muscle cramps and spasms, paresthesias, and tetany. Cardiac abnormalities include ventricular arrhythmias, heart block, and hypotension. Neurologic complications include confusion, delirium, and seizures. Treatment of asymptomatic hypocalcemia is generally not recommended, particularly in the setting of hyperphosphatemia. In patients with severe hypocalcemia, IV calcium gluconate (50 to 100 mg/kg/dose) may be administered to correct marked or life-threatening clinical symptoms. However, this treatment may increase the risk of calcium phosphate deposition.

Hyperuricemia

Hyperuricemia is defined as serum uric acid greater than or equal to 8.0 mg/dL or a 25% increase from baseline 3 days before or 7 days after the initiation of chemotherapy. The major route of urate clearance is through the proximal renal tubule, and thus hyperuricemia develops when the excretory capacity of the renal tubule is exceeded. In combination with an acidic pH, hyperuricemia can lead to the formation of uric acid crystals in the renal tubule, resulting in intraluminal renal tubular obstruction and the development of acute renal dysfunction. The current pharmacologic strategies for the management of hyperuricemia are allopurinol and rasburicase.

Allopurinol was first approved for clinical use by the U.S. Food and Drug Administration in 1966 to treat patients with gout.[116] An isomer of hypoxanthine, allopurinol is rapidly converted in vivo to oxypurinol, which functions as a competitive inhibitor of xanthine oxidase. This irreversible inhibition of xanthine oxidase prevents the metabolism of xanthine and hypoxanthine to uric acid (see Fig. 68-9). In 1965, one of the first studies to examine the use of allopurinol in persons with TLS reported that 15 patients with leukemia or lymphoma had lowering of serum and urine uric acid levels after daily administration of allopurinol during the initiation of therapy.[117] A similar study was published in 1966, in which 33 patients with chronic leukemia, acute leukemia, or lymphoma had a dose-related reduction in uric acid after treatment with allopurinol.[118] This agent has since formed the backbone of both TLS prevention and treatment.

Allopurinol is available in two preparations, oral and IV, and they have similar efficacies. However, the IV formulation is considerably more costly and should be reserved for patients who are unable to take oral drugs. Allopurinol is administered at a dosage of 100 mg/m^2 every 8 hours by mouth (maximum, 800 mg/day) or 200 to 400 mg/m^2/day in one to three divided doses IV (maximum, 600 mg/day). A significant limitation of allopurinol is that it cannot reduce uric acid produced prior to its initiation. Patients with hyperuricemia at presentation will not have a reduction in uric acid levels for 2 to 3 days after the initiation of allopurinol because the removal of existing uric acid is dependent on renal clearance.[119] Another concern is that treatment with allopurinol can lead to increased levels of the uric acid precursors hypoxanthine and xanthine via inhibition of xanthine oxidase. Because xanthine is less soluble than uric acid, it is possible that high levels of xanthine may lead to xanthine nephropathy or xanthine renal stones. The clinical significance of this hypothesis is not clear because xanthine nephropathy has been rarely reported. In a study of 19 children with ALL who received allopurinol for tumor lysis syndrome, precipitated xanthine was significantly more likely to be found in the urine sediment of patients with high urine xanthine levels (>350 mg/dL). However, no difference was found in the incidence of precipitated xanthine in patients who did and did not experience acute renal failure.[114]

Urate oxidase provides an alternate approach for treating hyperuricemia by promoting the catabolism of uric acid to allantoin. Compared with uric acid, allantoin is five to ten times more water soluble and is easily excreted in urine.[120] Urate oxidase is an endogenous enzyme found in many mammalian species but not in humans. A nonrecombinant form of urate oxidase purified from the mold *Aspergillus flavus* has been demonstrated to reduce uric acid levels in patients at risk for TLS and has been available in Europe for more than 20 years. In the United States, a pediatric trial of this nonrecombinant urate oxidase was conducted in 126 children with newly diagnosed non–B-cell ALL. When compared with historic control subjects who were treated with allopurinol, patients treated with urate oxidase had significantly greater decreases in their blood uric acid levels (median maximal level during treatment, 2.3 vs. 3.9 mg/dL; $P <$ .001).[121] However, the nonrecombinant urate oxidase was also associated with significant acute hypersensitivity reactions, including anaphylaxis, in 4.5% of patients receiving the drug.

Subsequently, a recombinant form of urate oxidase (rasburicase) produced by a genetically modified *Saccharomyces cerevisiae* strain has become available and appears to have a lower incidence of hypersensitivity reactions. Rasburicase offers a potential advantage over allopurinol by affecting the direct breakdown of uric acid and consequently leading to a more rapid lowering of serum uric acid levels. Faster normalization of uric acid levels also allows for earlier discontinuation of alkalinized fluids, which likely results in better excretion of other metabolites and avoids the increased risk of precipitation of calcium phosphate stones in the setting of overalkalinization. It should be noted that blood samples for uric acid measurement in patients receiving rasburicase therapy require special handling because of ex vivo degradation of uric acid by rasburicase at room temperature. To avoid falsely low uric acid levels, blood samples must be kept on ice and processed at 4°C within 4 hours of collection.

Pui and colleagues[122] initially administered rasburicase at a dose of 0.15 to 0.20 mg/kg IV for 5 to 7 days to 131 children with newly diagnosed leukemia or lymphoma. This study demonstrated a significant reduction of the median uric acid level by 4 hours after treatment, from 9.7 to 1 mg/dL in the 65 patients who presented with hyperuricemia and from 4.3 to 0.5 mg/dL in the remaining 66 patients. Rasburicase was very well tolerated in this study, with bronchospasm developing in 1 of 131 children. In addition, an open-label, multicenter, intent-to-treat, randomized, controlled trial was conducted to compare allopurinol with rasburicase in 52 pediatric patients with leukemia or lymphoma who were at high risk for TLS.[123] This study showed that patients randomized to rasburicase compared with allopurinol achieved an 86% versus 12% reduction of initial serum uric acid levels 4 hours after the first dose. In addition, no hypersensitivity reactions were observed in this study. Limitations of this study included its open-label design and the difficulty of generalizing these results to an adult population, although children up to age 17 years were included. Randomized controlled trials of allopurinol versus rasburicase have not been performed in the adult population.

Rasburicase is contraindicated in patients known to have glucose-6-phosphate dehydrogenase (G6PD) deficiency because the hydrogen peroxide generated in the breakdown of uric acid cannot be cleared by these patients.[120] The peroxide causes oxidative damage, resulting in hemolytic anemia and methemoglobinemia. The hemolytic anemia caused by rasburicase can be severe and can exacerbate renal damage in the setting of TLS. It is recommended that G6PD screening be performed before administration of rasburicase whenever possible.[124] Screening should be performed prior to transfusion with packed red blood cells to avoid false-negative results. If screening cannot be performed in a timely manner, the use of rasburicase should be avoided in patients who by ethnic background or family history have a significant risk of G6PD deficiency. Other adverse reactions associated with rasburicase include rare occurrences of hypersensitivity reactions, rash, increased liver enzyme levels, headache, vomiting, and nausea.[125] Because of the high incidence of hypersensitivity reactions associated with the nonrecombinant urate oxidase, several studies have measured antibody formation to rasburicase. In one study, no patients experienced hypersensitivity reactions and none of the 23 of 27 patient samples tested contained detectable levels of antibodies to rasburicase.[123] In another study, antibodies developed in 14% of patients, but none of these patients had hypersensitivity reactions.[123] It remains uncertain whether patients with detection of antibodies to rasburicase are at greater risk of hypersensitivity reactions with repeat courses. It has been suggested that patients with asthma and those with a high risk of hypersensitivity reactions based on allergy history should be monitored closely when receiving rasburicase.

Because of the high cost of rasburicase compared with allopurinol, it has been recommended that the use of rasburicase be reserved for patients with significant hyperuricemia at presentation or those at high risk of the development of severe TLS. The significant cost of rasburicase therapy has led several groups to evaluate the efficacy of single-dose therapy. Several published reports have demonstrated rapid reduction of uric acid levels with a single dose of rasburicase, with persistent effects for up to 7 days.[126,127] Thus single-dose therapy appears to be effective for both treatment and prophylaxis of hyperuricemia. However, when considering the use of rasburicase based on cost, it must be recognized that significant costs are also associated with complications of hyperuricemia and TLS, such as acute renal failure and dialysis. For example, a European study that examined the economic consequences of TLS management found that the main cost drivers in TLS are interventions requiring intensive care.[128] Thus studies aiming to analyze the cost difference between allopurinol and rasburicase should take into account the outcomes of acute renal failure and/or dialysis.

Uremia and Acute Renal Failure

Causes for renal dysfunction, azotemia, and rising creatinine levels can be multifactorial in persons with acute TLS. For example, any of the following conditions can result in renal injury: uric acid crystal obstructive uropathy, renal precipitation of calcium phosphate, renal tumor infiltration, xanthinuria, nephrotoxic drugs, or intravascular volume depletion. Despite appropriate medical management, some patients with increasing renal dysfunction and acute TLS require more aggressive measures, such as dialysis or hemofiltration. Indications for these therapies include metabolic derangements (e.g., hyperkalemia, hyperphosphatemia, hyperuricemia, hypocalcemia, and uremia) or volume overload that cannot be adequately controlled by medical management. Hemodialysis, peritoneal dialysis, and continuous hemofiltration (arteriovenous and venovenous) have been used in pediatric and adult populations for the treatment of TLS.[129-131] Peritoneal dialysis, although commonly used in many forms of acute renal failure, cannot be safely used in patients with intraabdominal tumors (e.g., Burkitt lymphoma) and is not recommended in the oncologic setting because of risk of infection in immunocompromised hosts.[115] The major advantage of hemodialysis compared with the other modalities is the rapidity with which electrolyte abnormalities can be corrected. However, hemodialysis can lead to large swings in plasma electrolyte levels and also can impose significant hemodynamic challenges. Continuous hemofiltration provides a more gradual method of correcting fluid and electrolyte disturbances and may serve as a safer alternative to hemodialysis in some cases. Unfortunately, little evidence relating to the comparison of the various dialysis modalities is available. Consultation with a nephrologist or an intensivist is recommended when weighing the options of hemofiltration and dialysis.

Conclusions

Tumor lysis syndrome is a constellation of metabolic derangements resulting from massive release of intracellular ions and nucleotides. Purine catabolism in the setting of TLS is particularly problematic for humans because of the lack of endogenous urate oxidase that can convert uric acid to the more soluble allantoin. The introduction of rasburicase has effectively reduced the incidence and severity of complications from hyperuricemia in patients at high risk for TLS. Although rasburicase appears to have great potential, many questions regarding its use remain unanswered.

COMPLICATIONS OF CHEMOTHERAPY

The use of chemotherapeutic agents carries risks for multiple acute and chronic toxicities and potential complications. Several oncologic emergencies related to the use of particular chemotherapeutic agents are summarized in this chapter. These emergencies must be recognized and managed effectively to prevent patient morbidity and mortality.

Vesicant Extravasation

Extravasation of vesicant chemotherapeutic agents can result in severe patient morbidity, with the development of extensive tissue damage. Vesicant agents include antitumor antibiotics (e.g., anthracyclines and dactinomycin), vinca alkaloids, epipodophyllotoxins, cisplatin, alkylating agents, and taxanes. Extravasation of anthracycline agents such as doxorubicin and daunorubicin can result in particularly severe and progressive tissue necrosis.[132] Importantly, the use of a central venous access device does not preclude the possibility of extravasation. Blood return or other evidence of patency, such as a dye study, is needed before a vesicant is administered in a central venous line. Once extravasation is suspected, usually because of swelling, redness, and pain at the injection site, administration of the agent should be stopped and assessment and treatment should be initiated.

Extravasation has traditionally been managed via the application of cold compresses, although this treatment is contraindicated with certain agents (such as vinca alkaloids and epipodophyllotoxins). Hyaluronidase may be used in certain situations to promote rapid dispersion of the infiltrate into surrounding tissue to lessen the severity of local tissue damage. Mechlorethamine extravasation can also result in tissue necrosis. The manufacturer recommends the local injection of sodium thiosulfate into the extravasation area, followed by topical application of ice. Vinca alkaloid extravasation management includes application of warm compresses and local injections of hyaluronidase.[133] Cooling the area has been recommended for taxane extravasation.[134]

Surgical debridement of affected areas may be required.[134] In 2007, the U.S. Food and Drug Administration approved dexrazoxane hydrochloride (Totect) for injection for the treatment of extravasation resulting from IV anthracycline chemotherapy.[135] In two studies, 57 evaluable patients underwent biopsy-proven extravasation of anthracycline from peripheral vein or central venous access sites. Totect was administered within 6 hours of extravasation for three doses, repeated 24 and 48 hours after the first dose. One patient required surgical intervention and the remaining patients had mild or no sequelae.[136] The use of Totect in the pediatric population has not been separately reported.

Methotrexate-Induced Renal Dysfunction

Because methotrexate is usually cleared exclusively by the kidneys, nephrotoxicity associated with high-dose methotrexate administration can be considered a true oncologic emergency. Although the strategies of hydration, alkalinization, and leucovorin rescue with close monitoring of methotrexate concentration and serum creatinine usually allow for safe administration of high-dose methotrexate, nephrotoxicity still occurs in some patients. Renal dysfunction was found to occur in approximately 1.8% of patients with osteosarcoma who were treated in clinical trials.[137] Renal dysfunction can result in persistently elevated methotrexate levels. Markedly delayed clearance of the drug amplifies methotrexate's other toxic effects, such as mucositis, hepatotoxicity, and myelosuppression.[138] In the patient with methotrexate-induced renal dysfunction, increasing leucovorin administration based on plasma methotrexate concentration remains a key intervention. Hemodialysis, hemoperfusion, therapeutic plasma exchange, and peritoneal dialysis have had limited success in this setting and may be useful in certain clinical situations.[137] Carboxypeptidase-G2 (known as CPDG2, glucarpidase, or Voraxaze), a recombinant bacterial enzyme, offers another emergency treatment option.[139,140] Glucarpidase provides hepatic elimination instead of renal clearance by metabolizing methotrexate to the inactive metabolite, 2,4-diamino-N10-methylpteroic acid.[141] Within minutes of administration, glucarpidase results in an average 97% reduction in plasma methotrexate concentration, allowing for continued management with leucovorin and supportive care. Glucarpidase is now commercially available and should be considered a standard component of treatment for patients with severe methotrexate-induced nephropathy.[142] Most cases of methotrexate-induced renal dysfunction resolve without long-term sequelae, and a single episode of nephrotoxicity does not automatically preclude future high-dose methotrexate use.[143]

Intrathecal Chemotherapy Overdose

Measures to prevent errors and overdose in the administration of intrathecal chemotherapeutic agents are key to avoiding this potentially devastating complication, and multistep safety systems have rendered these events rare in modern clinical practice. However, such errors continue to be reported, underscoring the importance of keeping plans for treatment and management in place in case such an adverse event occurs. Immediate response is crucial; case reports and small series highlight potential strategies.

Intrathecal overdose of methotrexate can result in seizures, coma, and death. Treatment options for intrathecal methotrexate overdose have traditionally included cerebrospinal fluid (CSF) drainage, ventriculolumbar CSF perfusion, systemic steroids, and systemic leucovorin.[137] Immediate removal of CSF has been advocated. The intrathecal use of leucovorin has not been advocated.[144] The intrathecal use of CPDG2 has also been reported.[145] In a 2004 report, Widemann et al.[137] presented results of a collaborative protocol assessing the intrathecal administration of CPDG2 in seven patients with cancer who had received accidental overdoses of intrathecal methotrexate, defined as a dose greater than 100 mg. These investigators found that methotrexate concentrations in the CSF declined by more than 98% in all patients and that all patients recovered completely from the overdose, except for two patients aged 61 and 77 years with memory impairment.[137] Four of the cases were pediatric cases, with ages ranging from 5 to 9 years. Three of these patients received a 600-mg dose of methotrexate, two underwent CSF exchange, and all were reported to have a complete recovery. It was concluded that CPDG2 should be considered for intrathecal methotrexate overdose.

One case report of an intrathecal overdose of cytarabine in a 4-year-old was managed with CSF exchange, and the patient survived.[146] At any dose, intrathecal vincristine is almost universally fatal and must be avoided at all costs.[147] As a result, the majority of active pediatric oncology practices have specific safety measures in place involving pharmacists, nurses, and physicians to prevent inadvertent administration of intrathecal vincristine. Clearly, preventive measures in prescribing, preparing, and delivering intrathecal chemotherapy remain essential.

HISTORY OF PEDIATRIC ONCOLOGY NURSING

Nursing is the largest health care occupation in the United States, representing 2.7 million jobs—a number that is expected to grow by 26% or more before 2020, faster than the national average of 14%.[1] Because its roots are embedded in daily life and the caretaking role women traditionally assumed throughout history, nursing was not recognized as a profession until the mid-1800s, when Florence Nightingale identified the need for specialized education and training and developed the underpinnings of modern-day nursing practice.[2]

The first nurses were considered generalists and cared for patients of all ages. Pediatric nursing emerged as a specialty in the early 20th century, when free-standing children's hospitals became more common.[2] During this time, pediatric oncology patients were often cared for by pediatric nurses (sometimes called tumor therapy nurses) who learned to care for oncology patients through experience and self-directed, on-the-job training.[3-5]

The subspecialty of pediatric oncology nursing first appeared in the late 1940s and early 1950s, when courses specific to cancer nursing were introduced by the American Cancer Society, the University of Washington, and the University of Minnesota School of Public Health.[1,4,6] It was formally recognized as a subspecialty practice in the mid-1970s, when more nursing schools began offering education specific to pediatric oncology, and a small cohort of nurses formed the Association of Pediatric Oncology Nurses (APON).[4,7,8] APON changed its name in 2006 to the Association of Pediatric Hematology/Oncology Nurses (APHON) and is considered the leading professional organization for registered nurses caring for children and adolescents with cancer and blood disorders.[9,10]

Over the years, the role of pediatric oncology nurses has evolved to match advances in cancer treatment. During the 1880s and early 1900s, the predominant treatment modality for cancer was surgery, and nursing care was focused primarily on relieving pain and meeting other postsurgical needs of patients.[6] Until the latter half of the 1900s, cancer was a metaphor for death and nurses had few resources available to care for the patients it affected. Children diagnosed with cancer commonly died, diagnostic techniques and treatment were often not available, and care was typically palliative.[4,5] The general attitude among health care professionals was that there was little to offer the person with cancer except a cheerful manner and a few comfort measures.[11]

After World War II, single-agent chemotherapy was introduced. This new therapy was administered only by physicians until the 1960s, when it was proposed that nurses assume this responsibility.[6] Today, chemotherapy is almost always administered by nurses, who as a discipline have been instrumental in developing standards for safe practice and education related to chemotherapy administration and symptom management.[7,12-14] Pediatric oncology nurses are also leaders in patient and family education, pain management, and palliative care. Over the past few decades, a number of advanced-practice nursing roles have gained prominence. The term *advanced practice nurse* applies to nurses in specialized roles, including clinical nurse specialists, nurse practitioners, certified nurse midwives, and nurse anesthetists, who have completed additional formal education and training. In pediatric oncology settings, it is the clinical nurse specialist and the pediatric nurse practitioner who are most commonly employed. Although their responsibilities vary among institutions, the clinical nurse specialist generally focuses on the education of the staff and of patients and families, whereas the pediatric nurse practitioner usually provides direct patient care in consultation with the patient's oncologist. As a primary oncology provider, the pediatric nurse practitioner follows patients and families over time and helps to formulate, implement, and evaluate the patient's plan of care. Depending on institutional, state, and federal regulations, a pediatric nurse practitioner may also prescribe medications and perform procedures, such as bone marrow biopsies and lumbar punctures. Standards and guidelines regarding professional behaviors and scope of practice developed by APHON and the American Nurses Association also guide the practice of advanced practice nurses.[15]

Each year, 10,000 children will receive a diagnosis of childhood cancer and 1.16 million children younger than the age of 15 years will be hospitalized with a cancer-related diagnosis.[16,17]Although the incidence of pediatric cancer has increased 29% during the past 20 years, advances in treatment have resulted in a long-term childhood survival rate of 79% for all childhood cancers.[18,19] Some selected childhood cancers have realized long-term survival rates that now approach or exceed 95%.[16,18] Despite improving statistics where the 10-year survival rate is 75%, cancer is the second leading cause of death in children from birth to age 14 years.[20] Pediatric oncology nurses at all levels will continue to play critical roles in the care of children with cancer as new diagnostic and treatment techniques become available. Through persistence, vigilance, and dedication, nurses will shape the development and modification of practice standards that promote safe and effective pediatric cancer care.[7,21]

Nursing Education and Professional Certification

When nursing first emerged as a profession, nursing education was typically provided by hospital-based diploma programs.[22] Today, most diploma programs have closed and have been replaced by college- and university-based schools of nursing. Nurses specializing in pediatric oncology usually receive advanced training in all aspects of cancer and cancer treatment, including chemotherapy, management of complications related to therapy, pediatric oncology protocols, and the protection of human subjects.[23-25] In addition to this specialized training, APHON and most health care organizations recommend that pediatric oncology nurses obtain professional certification as another vehicle to confirm proficiency and demonstrate knowledge of pediatric oncology practice standards, although it is not a requirement for practice. Certification was first introduced in 1999, and since then more than 1700 registered nurses have become certified pediatric oncology nurses.[26,27-29]

OVERVIEW OF THE PEDIATRIC ONCOLOGY NURSE'S ROLE

The role of the nurse in the care of childhood cancer patients is well established.[30] Pediatric oncology nurses rely on their intellect, critical thinking abilities, expert communication skills, technical expertise, and up-to-date knowledge when caring for their patients.[25,31,32] These skills, when combined with intuition and caring, position pediatric oncology nurses to actively participate in and influence decisions concerning patient care and support, promote novel approaches to care, and optimize patient outcomes.[31-33]

When caring for patients, pediatric oncology nurses integrate information about the treatment modality with observations of how the patient and family are responding to treatment and whether additional education and support are needed. Much of a pediatric oncology nurse's practice is grounded in standards of care and professional performance defined by APHON. These standards apply to clinical settings across the continuum of care and serve as a guide for nurses practicing in all aspects of care, from prevention, early detection, ongoing physical and psychosocial care, and long-term survival. These standards of care also define activities associated with each step of the nursing process—a process that includes assessing the patient, identifying problems requiring nursing intervention, specifying expected outcomes, planning and implementing a nursing plan of care, and evaluating the child's progress (Table 69-1).[15] With the patient as the central

TABLE 69-1 The Nursing Process and Standards of Pediatric Oncology Nursing Care

Nursing Process	Standards of Care	Application: Case Study*
Assessment	The pediatric oncology nurse collects and documents data regarding the child and family.	• Obtained a patient history of severe chemotherapy-related nausea and vomiting during first treatment regimen.
Diagnosis	The nurse uses assessment data from nursing and other disciplines to identify problems and determine nursing diagnoses.	• Severe chemotherapy-related nausea despite antiemetics • New protocol regimen is highly emetogenic. • Assess the need for overnight hydration or next-day clinic infusion appointment for bolus to help with nausea control.
Outcomes Identification	The nurse identifies expected and desired outcomes specific to the patient and family and related to their physical and emotional health, education, growth and development, and effects of disease and treatment.	Expected outcomes: • Patient will experience little or no nausea during chemotherapy and postchemotherapy period. • Patient and family will communicate effectiveness of antiemetic and patient satisfaction with the regimen.
Planning	The nurse develops an individualized plan that prescribes interventions to attain expected outcomes.	• Resume previous antiemetics (ondansetron, corticosteroids, and scopolamine). Add new antiemetic, aprepitant. • Have patient maintain a diary describing nausea and individual drug effectiveness.
Implementation	The nurse implements the plan of care to achieve the expected outcomes for the child and family.	• Administer first antiemetic doses in clinic to monitor effectiveness, and review timing of doses.
Coordination of Care	The nurse coordinates the delivery of care to support transition across the continuum of care.	• College student describes past use of dronabinol and lorazepam to control nausea. Patient states that these agents made him feel "loopy" which impeded his ability to attend class and keep up with studies.
Health Teaching and Health Promotion	The nurse employs strategies to educate patient and family about maintaining health and providing a safe environment of care.	• Provided a detailed calendar outlining scheduled chemotherapy, predicted times of nausea, medication schedule, and escalation plan for unresolved nausea • Reviewed patient education materials associated with prescribed antiemetic agents. • Reviewed prn use of additional antiemetics
Evaluation	Working with other members of the care team, the nurse evaluates outcomes that have been achieved and follows the nursing process to adjust the plan of care as needed.	• Patient returned for cycle 2. Reviewed the drug diary with the patient to understand the duration of nausea and the patient's perspective on the effectiveness of the antiemetic regimen. • Patient reported no nausea, did not require supplemental antiemetics, and reported increased satisfaction with plan, noting that he had previously found the inability to control nausea extremely distressing.

*Applying the nursing process to the management of postchemotherapy nausea in a 19-year-old college student with relapsed Ewing sarcoma. Case study of a patient at Dana-Farber/Children's Hospital Cancer and Blood Disorders Center managed by primary nurse A. Carnes, BSN, RN, CPON.

focus, the ultimate goal is to reestablish a level of optimal wellness as defined by the patient and family.[34] The nursing process is dynamic and considers all dimensions of care; therefore, the plan of care is continually adjusted in response to changes in the patient's condition and treatment plan.[34]

As discussed in this chapter and highlighted in Box 69-1, pediatric oncology nurses are critical members of the oncology team, collaborating with colleagues and using an evidence-based approach to reduce the burden of cancer and meet the needs of patients and families.

The Nurse's Relationship with Patients, Families, and Other Providers

Meeting the varied needs of pediatric oncology patients and their families requires a broad range of professionals. For this reason, most pediatric cancer centers draw on an interdisciplinary team, replacing the physician-centered model that was more common in the early years of cancer care.[3] Today, members of the care team rely on one another's observations, knowledge, and skills, with physicians and nurses working as interdependent partners toward the care and cure of children with cancer.[5,35,36] Equally important is coordinated and ongoing interaction between the child, the family, and all members of the interdisciplinary team.

Patient- and Family-Centered Care

Partnering with patients and families is the cornerstone of patient- and family-centered care. A model of care delivery commonly practiced in pediatric oncology settings is based on the understanding that the family is the child's primary source of strength and support, that the perspectives and information provided by the family,

Box 69-1 **The Role of the Pediatric Oncology Nurse in Reducing the Burden of Cancer: Ensuring Families' Needs Are Met**

CARING PRACTICES

- Provides compassionate, developmentally appropriate care
- Considers cultural differences when developing and implementing a plan of care
- Minimizes pain and suffering
- Partners with patients and families to individualize approaches to care
- Develops and coordinates all aspects of patients' experiences across the continuum
- Collaborates with other disciplines to ensure optimal patient care
- Demonstrates caring practices toward all patients, families, and members of the health care system

COMMUNICATION AND COLLABORATION

- Serves as an advocate for the needs of the patients and families
- Exchanges ideas with other members of the clinical team to advance clinical practice and patient care
- Facilitates communication:
  - With the community
  - With the patients and families
  - Between the patients and physicians
  - Between the patients and other members of the health care team

EDUCATION AND LEARNING

- Teaches patients and families about the cancer diagnosis and its treatment
- Prepares patients and families to manage home care needs and transition back into the community
- Encourages techniques supporting compassionate clinical and emotional care
- Educates other members of the clinical team
- Creates educational materials for patients, families, and other health care providers
- Influences nursing practice at a local, national, and international level

CLINICAL INQUIRY AND SYSTEMS THINKING

- Uses clinical judgment and reasoning to care for patients effectively
- Guides pediatric oncology nursing practice by identifying key research areas
- Advances nursing science using the best available evidence as the basis for changes in practice
- Masters the skills and competencies necessary to maximize clinical outcomes
- Serves as a change agent
- Critically examines the environment, identifies opportunities for change, and introduces strategies to ensure safe care

the child, or the young adult are important to clinical decision making, and that the psychosocial and cultural needs of the family as well as the patient must be considered throughout the care process.[21,37,38,39] Guidelines developed by the Institute for Patient- and Family-Centered Care for clinicians interested in adopting a patient- and family-centered care model (Box 69-2) emphasize the importance of partnering with the patient and family throughout the course of treatment. Respecting the insights and perspectives of the parents regarding their child's needs, empowering the patient and family by providing them with information, and engaging the child in his or her own care are key aspects of the model. Organizations are also urged to involve patients and families in defining and improving institutional policies and care delivery systems.[37]

Although patient- and family-centered care is now widely embraced by pediatric health care professionals, there was a time when parental visitation was permitted only on a limited basis, information related to a child's diagnosis was often withheld from the patient and the family for fear of increasing anxiety, and decisions surrounding care were made within a paternalistic framework.[21,40] Nurses were often caught in the middle when a patient did not know the diagnosis or the family was not involved in shared decision making.[6,21] The cultural shift to a family-centered focus, along with improvements in survival rates, have helped members of the health care team develop a keener understanding of the long-term effects of diagnosis and treatment as well as an appreciation for how physiologic and psychological sequelae impact the patient and their family members.[21] The patient- and family-centered approach has also helped parents to gain confidence in their ability to care for their child throughout the course of illness and has helped children and young adults to manage aspects of their own health care.[37] Nurses routinely partner with patients and families throughout the cancer patient's care, from diagnosis to end of life, involving patients and families in establishing short- and long-term goals. This is particularly important for children because it gives them a feeling of control and enhances their sense of autonomy.[41] Although the ability of the child to participate in goal setting and decision making depends in part on their maturity and cognitive capacities, approaches and techniques usually can be tailored to match their capabilities.

Meeting the Emotional and Developmental Needs of Patients and Families

Pediatric oncology nurses often spend long stretches of time with patients and families, particularly when patients are hospitalized or receiving outpatient chemotherapy.

Box 69-2 **Patient- and Family-Centered Care: Guidelines for Providers**

- **Respect and dignity.** Health care practitioners listen to and honor patient and family perspectives and choices. Patient and family knowledge, values, beliefs, and cultural backgrounds are incorporated into the planning and delivery of care.
- **Information sharing.** Health care practitioners communicate and share complete and unbiased information with patients and families in ways that are affirming and useful. Patients and families receive timely, complete, and accurate information to effectively participate in care and decision making.
- **Participation.** Patients and families are encouraged and supported in participating in care and decision making at the level they choose.
- **Collaboration.** Patients and families are also included on an institution-wide basis. Health care leaders collaborate with patients and families in policy and program development, implementation, and evaluation; in health care facility design; and in professional education, as well as in the delivery of care.

From the Institute for Patient- and Family-Centered Care: www.ipfcc.org.

Because of their frequent interactions with patients and families, nurses are often the first to recognize practical issues faced by families. Over time, many families view nurses as advocates; however, the nurses' role is not to provide all of the support families need but rather to nurture support systems and identify available resources that might be of help.

Developing trusting relationships with patients and families is essential to effective oncology nursing practice.[41] Nurses often gain this trust simply through the care provided, the hours spent at the patients' bedsides, and the efforts undertaken to meet the needs of patients and families while facilitating communication with other providers. Among children and adolescents, trust is often more readily gained when the actions of the nurse reflect an appreciation for developmental needs and when nurses are forthright, honest, and maintain developmentally appropriate boundaries regarding the behavior of the child or adolescent.[42-44]

In addition to the emotional needs of patients and families, children undergoing treatment for cancer are at risk for significant delays in growth and development, which are often functions of the length and type of treatment and the side effects that children experience.[45] Therefore, nurses caring for children with cancer incorporate developmentally supportive care into all phases of treatment. Such care requires knowledge of normal growth and development as well as an appreciation for the variations and abnormalities that may be encountered among children who are ill. A variety of approaches are used to support a patient's growth and development to help them reach their maximum personal potential. Providing age-appropriate care individualized to each patient, encouraging parental involvement, and fostering normalcy whenever possible by maintaining routines and usual activities are just a few of the strategies nurses use. Child-life specialists are routinely consulted to establish interventions for hospitalized children that are appropriate to developmental milestones.[46,47]

Educating Patients and Families

A hallmark of comprehensive pediatric oncology care is educating patients and families about the diagnosis and treatment, empowering them to make informed decisions and become active partners in the treatment process.[48,49-51] Because the care process typically spans multiple settings, patients and families are likely to receive information and instruction from a variety of clinicians and care providers. As a matter of course, teaching is a part of most patient encounters to help patients and families build skills and gain the self-confidence necessary to actively participate in ongoing care processes. When teaching patients and families, nurses adapt teaching methods to meet the educational needs of individual patients and families. Nurses supplement didactic instructions with written materials that augment topics covered in teaching sessions. Frequent opportunities to observe and practice the skills needed to manage care at home are typically offered. The use of technology for simulation and teaching is increasing as new educational formats become available.

Nurses have been instrumental on local, national, and international levels in developing educational materials for parents and age-appropriate materials for patients. In many hospitals and other care-delivery settings, nurses coordinate efforts to develop and evaluate educational materials on a wide range of topics, have the materials translated into various languages, and make them accessible to patients and families. A number of nursing organizations have also developed education resources. For example, APHON has developed a wide range of disease-specific pamphlets and education programs for patients and families that outline treatment options, side effects, and how to care for children at home.[52] The Children's Oncology Group also offers an informative website, a handbook, and numerous networking opportunities for parents.[53]

CARING FOR PATIENTS AND FAMILIES DURING THE DIAGNOSTIC PHASE

Receiving a diagnosis of childhood cancer is devastating and life altering.[54] For parents, the diagnostic phase is marked by extreme emotional, physical, and spiritual distress, with many describing the period of waiting and not knowing as one of the most difficult times in the journey.[55-57] It is during this waiting period that parents are often acutely aware that cancer is the probable diagnosis, but the type of cancer, the expected treatment, and the likely outcome have yet to be determined.[57] As a result, this is a time of uncertainty, with many fears stemming from the unknown and questions the clinical team may not yet be ready to answer. Some of the questions known to be plaguing the parents during this phase include the following: Will our child survive? What will the future hold? Will our child suffer? Will we be able to comfort and protect our child from pain?[51,56]

The nurse caring for a child suspected of having cancer is in a unique position to assess needs, identify cultural preferences, offer support and guidance, as well as ensure access to information needed to provide informed consent.[55,58] Because this period typically involves interactions with a variety of health care providers, the nurse supports coordination of this process to optimize communication between the patients and families and members of the health care team.[59] To do this, the nurse must possess a thorough understanding of the prediagnostic and diagnostic phases of pediatric malignancies that include, but are not limited to, the various tests and procedures commonly used for diagnosis.[55]

The Diagnostic Workup

Confirming a cancer diagnosis can be a long process because many of the initial symptoms imitate normal childhood illnesses.[55] The diagnostic workup includes obtaining a complete history of the current illness, the incidence and duration of symptoms, and the existence of any predisposing factors.[60] It is during this phase that the nurse completes a comprehensive assessment that includes a physical examination, developmental assessment, and measurement of vital signs, height, and weight. The height and weight are used to calculate the body surface area, a key measure if cancer is confirmed because it is used to determine chemotherapy doses in patients 1 year of age and older (weight in kilograms, rather than body surface area, is typically used to calculate doses for children younger than 1 year). Accurate measurement of body surface area is critical; therefore, it is common practice to have two nurses independently measure the initial height and weight and verify the calculations of body surface area.

Because the diagnostic phase involves numerous tests to determine the extent of disease, the nurse's role is focused on collecting specimens, coordinating the scheduling of the diagnostic workup, and partnering with the patient and family.[60] The nurse not only is responsible for ensuring that preparative regimens for specific tests are observed but also must facilitate the sequencing of various tests to ensure that procedures do not conflict with one another, that sufficient time is allotted for traveling from one department to another, and that tests are scheduled in a manner that permits judicious use of sedation.[60] Before each test, the nurse speaks with the patient and family explaining the test and how long it will take, discussing whether a contrast medium or sedation will be used, and answering any questions they may have about the procedure.

The diagnostic phase is emotionally and physically difficult, with diagnostic tests provoking anxiety and causing pain. Studies regarding the patient perception of pain suggest that the pain associated with invasive procedures and ultimate treatment for cancer is greater than the pain associated with the disease itself.[61,62] Fortunately, there are a wide array of pharmacologic and nonpharmacologic interventions available to minimize distress associated with pain and anxiety.

Informing Patients and Families of the Diagnosis

Once the diagnostic workup is complete and the type and extent of the cancer is known, news of the diagnosis is shared with the parents or guardian during a meeting with the physician and nurse. In some centers, this meeting is called the "Day One Talk." The purpose of this meeting is to review the extent of the disease, discuss the proposed treatment, consider whether alternatives to that treatment are available, and introduce and obtain informed consent in the patient's preferred language. If the proposed treatment is a research protocol, all issues related to the protocol, including the intent of the research, must be clearly explained to ensure informed decision making.[57] Studies regarding informed consent have found that parents of pediatric cancer patients often do not understand some of the issues related to participating in clinical trials, particularly that the purpose of research may be to benefit future patients rather than their own child.[63]

The Day One Talk typically represents the first step toward developing the patient-provider relationship forming the basis for future care. Determining who should be present during the meeting is not always simple, and parents often ask the physician or nurse for advice about whether the patient should be in attendance. Consideration should be given to including adolescents because they may assume that information later received is not completely true and that the diagnosis and treatment are worse than those stated in the information they have been given.[57] Including adolescents from the beginning may also help in later efforts to engage them in their own care. In cases involving younger children, a separate discussion tailored to the developmental level of the child is suggested, with the goal of informing the child about the treatment and clinical trial to obtain assent.[60]

Receiving the news that a child has cancer and hearing the complex treatment plan can be devastating for parents who may be overwhelmed with feelings of anger, fear, guilt, sadness, and self-blame. Because of this, parents may have difficulty retaining, processing, and understanding the information. The signed consent form detailing the aspects of treatment and chemotherapy information sheets may serve as useful references for parents after the meeting.[57]

If the patient is an adolescent, consideration must be given to the potential impact the treatment may have on fertility, as well as possible fertility-preservation options. It is generally recommended that this conversation take place as early as possible before beginning treatment. Some physicians choose to discuss fertility-related issues during the Day One Talk with a follow-up referral to reproductive specialists.[64]

Supporting Patients and Families after Diagnosis

After the Day One Talk, nurses provide ongoing support as patients and parents express fears and concerns. Once the diagnosis is made, patients and families are suddenly thrust into a complex plan of treatment that involves hospitals, ambulatory clinics, and home care agencies. Nurses help to arrange and coordinate appointments and other aspects of treatment, as well as facilitate collaboration and communication among care providers in various locations. During the weeks and months after the diagnosis, nurses carefully monitor patients and families for signs that suggest they may be having difficulty coping. If any signs of distress are observed, nurses work with colleagues on the health care team to formulate a plan to help patients, parents, and other family members manage their stress to enhance the family's chances for the best possible outcomes.[51] Many patients, parents, and family members benefit from working with psychosocial clinicians, attending family support groups, or having regularly scheduled family meetings, whereas others may require more intensive interventions.

NURSING IMPLICATIONS OF PEDIATRIC CANCER TREATMENT

The treatment of childhood cancer has evolved into an increasingly complex set of treatment modalities and methods. Although advances in treatment are responsible for marked improvements in survival rates, they have resulted in a broad range of side effects that require diligent monitoring and supportive therapy. Knowledgeable and well-trained pediatric oncology nurses are crucial to the safe and effective implementation of surgical, radiologic, and pharmacologic approaches to cancer treatment as well as to the management and oversight of clinical trials.

Nurses interact with patients during each treatment phase and in every care setting, making critical assessments and observations that guide decisions regarding the patients' care. Administering care specified by the treatment protocol, nurses continually monitor patients for complications and unexpected developments, offer emotional support to the patients and their families, and teach them what to expect during each treatment phase. Throughout the weeks, months, and years of care, nurses often develop a strong rapport with patients and families, becoming trusted sources of support and information.

Nursing Care Associated with Various Modes of Treatment

In this section, the specialized nursing care associated with the primary forms of pediatric oncology treatment—surgery, chemotherapy, radiation therapy, biotherapy, and hematopoietic stem cell transplant—are discussed. Complementary and integrative therapies and the nurse's role in clinical trials are also examined.

Surgery

Surgery is a major treatment approach for many pediatric solid tumors. Preoperative nursing care involves preparing patients and their families for the expected surgery and recovery by providing individualized teaching that is tailored to meet the unique needs of each patient and their family. In an effort to demystify the surgical experience, many hospitals offer programs that allow patients to visit the inpatient surgical unit, meet operating room nurses and other members of the staff, and see much of the equipment that will be used as part of the intraoperative care.[65]

During the postoperative period, nurses support the recovery process and promote healing. Close monitoring of vital signs and the overall clinical status, coughing and deep breathing, frequent position changes, and early ambulation are just a few of the nursing interventions introduced after surgery to prevent complications. Comprehensive postoperative care includes ongoing assessment of airway clearance, level of pain, signs and symptoms of fluid shifts, and infection. Fever is a common postoperative complication warranting careful monitoring and prompt treatment in pediatric oncology.[66]

Controlling postsurgical pain is a primary focus. Pain can have a profound effect on physical and emotional well-being, as well as discourage children from engaging in activities that promote recovery. Medications for pain control are typically initiated intraoperatively and are commonly continued for at least 72 hours after surgery or until the child is able to take medication by mouth.[67-70] During the postoperative period, nurses regularly assess for the presence of pain and the effectiveness of prescribed analgesics by observing the patient for signs of discomfort using age-appropriate pain-rating scales. Analgesics may be administered prior to activities such as walking or dressing changes to promote comfort and reduce the anxiety associated with procedures or activities that may cause pain.

Preparing patients and their families for discharge from the hospital after surgery typically begins before or at the time of admission. Discharge teaching involves a review of the care regimen, as well as coaching caregivers on how to perform aspects of physical care at home. Emphasis is placed on ensuring caregiver understanding of the signs and symptoms of potential complications, when they should contact a provider, and how to reach someone in the case of an emergency. Follow-up appointments with the surgical team and pediatric oncology providers are usually scheduled before discharge.

Chemotherapy

Chemotherapeutic agents are considered high-risk medications because of their narrow therapeutic index and the complexity of the treatment regimens in which they are used. If administered inappropriately, there is the potential for serious harm and even death.[71] Unlike other medications, administering chemotherapeutic agents to children introduces challenges because of the physiology of children, broad dosing ranges and schedules, widely differing protocols, weight-based dosing, and a high risk for toxicities.[13,14,72,73] Statistics revealing the incidence of medication errors have triggered widespread changes and standardization with all aspects of the medication process, from prescribing, dispensing and administration. The majority of medication errors occur at the time of administration (41%), followed by dispensing errors (38%) and prescribing errors (21%)[74] Because administering chemotherapy is the primary responsibility of pediatric oncology nurses, they are commonly viewed as the patient's last line of defense against medication errors.[75] Therefore, the provider may be viewed as the first line of defense with prescribers initiating the medication process. Because prescribing errors related to chemotherapy agents can have serious and even lethal effects, nurses in most institutions follow a special process to verify chemotherapy orders before the agent is administered. Each step of the verification process is designed to ensure chemotherapy is administered safely, the treatment protocol is observed, required pretreatment test results are within acceptable ranges, and the correct chemotherapy agent and dose are administered.[76] To minimize the risk for error, nurses complete specialized training and follow standards of practice for chemotherapy administration developed by APHON. In addition, they receive ongoing education relative to new agents and protocols before any new agents are introduced.[71]

Before administration of chemotherapy to a patient, the nurse reviews the patient's medical record and interviews the patient and family to determine past experience with chemotherapy, level of tolerance, and antiemetics used. During the interview, the nurse explains the current treatment plan, discusses each agent, reviews potential side effects, and completes a medication reconciliation process. The medication reconciliation process includes a review of chemotherapeutic agents, antiemetics, over-the-counter preparations, as well as herbal and nutritional supplements taken since the last visit. Querying the patient and family about medications reinforces an understanding of the treatment plan and medication doses providing an opportunity to evaluate compliance with the prescribed plan. The nurse also conducts an assessment to determine drug-specific side effects (e.g., constipation) to determine whether the chemotherapy can be administered as prescribed and if the symptom management plan should be adjusted.[73,77]

Because many chemotherapeutic agents are highly toxic, the National Institute of Occupational Safety and Health has developed standards to protect health care workers when handling or administering chemotherapy and caring for patients who have received chemotherapy.[78] The standards identify personal protective equipment such as gowns, gloves, and eye shields that must be worn by those handling chemotherapeutic agents. In addition, standards recommend the use of closed-system drug transfer devices to prevent accidental disconnection and exposure. Research has shown that complying with these standards limits long-term exposure.[79] Although some patients and families may be frightened when they first see nurses and other clinicians using protective equipment and procedures, most are quickly accepting once they understand the rationale for such measures. The safety concerns and precautions related to chemotherapy administration also apply to the patient's family, who must learn how to handle chemotherapeutic agents and the patient's body fluids. Body fluids can be a source of cytotoxic drugs and may pose a threat to the environment. As a result, special precautions for their disposal must be observed for 48 hours after chemotherapy administration, and family members should be given appropriate personal protective equipment and written instructions on how to handle the fluids safely. Family members of child-bearing age or who are pregnant should not prepare or administer cytotoxic drugs in the home. If they must handle the agent, they should minimize their risk by wearing appropriate protective equipment.[78]

During the time a patient is receiving a dose of chemotherapy, the nurse monitors parameters specific to the particular agent. In addition to monitoring temperature, blood pressure, and heart rate, the nurse observes the patient for signs of an allergic reaction and watches the access site for signs of possible extravasation or leakage of intravenous fluid into the tissues. Special precautions must be taken to prevent extravasation when administering a vesicant because these agents can cause blistering, severe tissue injury, or tissue necrosis if they extravasate.[80] If extravasation does occur, institutional polices and guidelines typically determine the appropriate actions to take.

After the chemotherapy has been administered, the nurse evaluates the effectiveness of the antiemetic regimen and monitors the patient for signs of toxicity and adverse effects. Detecting adverse effects early and taking quick action can minimize their severity. The nurse records the patient's response to treatment carefully because these observations are used by the care team to evaluate tolerance to treatment and determine whether changes need to be made in the overall plan of care.

For many families, the chemotherapy treatment phase is particularly difficult because they must cope with their own fears and anxieties while supporting the child or adolescent through treatment. Families often turn to the nurse for support and reassurance and find it comforting to work with a familiar and trusted team of nurses and providers. In some cases, families are asked to administer chemotherapy at home. Nurses work closely with these families to establish administration schedules, learn how to prepare and administer each medication safely, and understand which side effects to watch for and report (Box 69-3). They also teach the family about special considerations related to administering some agents. Most protocols and manufacturers now include specific instructions for these situations.

Box 69-3 **General Guidelines for Administering Chemotherapy by Family Members in the Home: What Families Need to Know**

1. Treatment goals and plan, including the length of treatment, number of cycles and days of treatment
2. A schema or calendar that shows the general treatment plan
3. Names of all medications (brand and generic)
4. Indications for all medications
5. Doses of all medications, including the strengths
6. How to administer the medications
    a. Safe handling (e.g., disposal of waste products and management of chemotherapeutic exposure or spill)
    b. How to measure the medications, especially liquids
    c. What foods or drinks the medications can be mixed with or taken with
    d. What foods or drinks to avoid when taking the medications
7. How and when to take the medications (e.g., before or after meals, at bedtime)
8. The start and stop date or criteria for stopping
9. Expected and potential side effects and preventive measures for side effects
10. When to report side effects and whom to call

Data from references 71 and 77.

Radiation Therapy

Radiation therapy is a common form of treatment for pediatric malignancies. The advancement of new technologies such as proton beam therapy is promising. Evidence, however, is still emerging regarding the potential role these new technologies will have in maximizing disease control and achieving high-quality survivorship.[81] Often administered in an outpatient setting for a number of consecutive days and weeks, radiation therapy can have significant side effects in children. As part of the treatment planning process, most patients undergo radiation simulation to determine the radiation field. Simulation requires the use of markings, blocks, and immobilization devices to ensure that the radiation will be delivered consistently to the same location during each radiation session. Children younger than 4 years of age usually require sedation and central venous access for their simulation and radiation treatments.[82,83] Children between 4 and 6 years of age may be able to tolerate the sessions without sedation if distraction techniques and nursing support are made available. Children older than 7 years of age usually tolerate the treatments well and are able to cooperate during the sessions.[83]

Nursing care for a child undergoing radiation therapy includes discussing the treatment plan with the patient and family, describing what the simulation process involves, assessing the patient for side effects, and educating the patient and family how to prevent and manage side effects. Because the side effects of radiation therapy are related to the site that is irradiated, interventions to alleviate them vary accordingly. The mouth and skin are commonly affected, and all patients and families are taught proper mouth and skin care techniques before they begin treatment. Patients receiving radiation therapy in combination with chemotherapy or biotherapy are monitored closely because certain agents can produce an exacerbated effect known as radiation recall, a severe rash that requires special precautions and treatment.[82,83]

Biotherapy (Biologic Response Modifiers/Biologic Therapies/Targeted Therapy)

In recent years, biotherapy, also known as biologic response modifiers (BRMs), biologic therapies, and targeted therapy, has emerged as a treatment modality using immunologic mechanisms to eradicate tumor cells.[84] Biotherapy agents include a wide range of products such as vaccines, blood and blood components, allergenics, somatic cells, gene therapy, tissues, and recombinant therapeutic proteins.[76] For example, there are vaccines to help prevent cancers as well as those designed to treat cancer. Vaccines, such as the human papillomavirus vaccine, help protect against certain strains of viruses and ultimately may prevent some cancers. Alternatively, vaccines that treat cancers are intended to increase the patient's immune response with the goal of attacking cells with one or more specific antigens.[85]

Biologic therapies interact with the child's immune system to enhance the response to cancer and may cause toxicities influenced by the dose, route, and schedule of administration. The most common side effect of biotherapy is a flulike syndrome characterized by fever, chills, rigors, myalgias, headache, and fatigue.[86] The role of the nurse in caring for the patient receiving biotherapy includes obtaining baseline vital signs, administration of any prescribed medications, and close monitoring for side effects. During and after administration, the nurse observes the patient for tachycardia, hypotension, fever, chills, anaphylaxis, and signs of a local reaction. Nurses also teach the patient and family about potential side effects that might occur at home, when such side effects should be reported, and symptom management techniques.[86]

Hematopoietic Stem Cell Transplant

Hematopoietic stem cell transplant (HSCT) involves the intravenous infusion of autologous or allogeneic stem cells.[87] This modality is used to treat malignant and nonmalignant diseases, and more than 4000 HSCTs were performed in 2009-2010 in patients younger than the age of 20, revealing a 20% increase from 1993-1994.[87,88] Since its development in 1939 there have been advances in cell source; improved conditioning regimens; more exact human leukocyte antigen typing, thus improving donor and patient matches and increasing overall transplant survival; decreased incidence and severity of acute and chronic graft-versus-host disease; and improved rates of engraftment.[88,89]

In an effort to promote improvement in cellular therapy, regenerative medicine, and patient outcomes, more than 85% of all transplant facilities in the United States partner with the Foundation for the Accreditation of Cellular Therapy (FACT).[90] Founded in 1996, FACT has established standards for clinical and laboratory departments that apply to hematopoietic progenitor cells and other cells obtained from hematopoietic sources that include marrow, peripheral blood, and umbilical cord blood.[90] These standards are focused on processing the clinical use of cellular therapy products as well as ensuring that they are collected and processed using strict controls.[90] The primary role of the registered nurse is to participate in the coordination of the transplant and to ensure FACT standards related to nursing practice are understood and adhered to.

Preprocedure Phase. There are 75 pediatric FACT accredited HSCT centers in the United States.[90] As a result, many patients change providers and transfer care to one of these institutions for the duration of HSCT treatment. Nurses may help to facilitate patient transfer by coordinating aspects of the referral process, clinical evaluation, or preprocedure education in the patient and family's preferred language and counseling. The period before HSCT can be one of great anxiety for patients and families. Good communication between the referring institution and the transplant center helps to ensure a smooth transfer process and fosters trust between the families and the new provider. Preprocedure processes vary among institutions; however, most are focused on an exchange of information needed to appropriately plan for the transplant.

Inpatient Care. Although hospital mortality and complications after HSCT have decreased, hospital length of stay ranging between 2 weeks to several months requires an experienced, culturally competent multidisciplinary team.[91] Specially trained nurses familiar with the immune and hematopoietic systems, stem cell transplant concepts, and complex treatment protocols are key members of the team playing critical roles during each phase of the treatment process.[78] After admission, a core team of nurses is usually established to develop an individualized nursing plan of care and oversee the patient's nursing care throughout the hospitalization. By understanding the risk factors and potential complications associated with HSCT, the nursing team works closely with all members of the health care team to evaluate and revise the plan of care as needed. Throughout the patient's hospitalization nurses support the patient and family to ensure their understanding of the process, which includes careful monitoring, assessing the patient for side effects, and understanding adverse reactions associated with each type of transplant.[92]

Planning for discharge typically begins early in the hospitalization and becomes a higher priority as engraftment approaches. The nurse assists in the coordination of discharge, offering emotional support and providing education necessary to facilitate the transition of the patient and family back home. Discharge teaching should include instructions in the preferred language of the patient concerning medications that must be taken after discharge, the ambulatory treatment plan, the care that must be administered in the home, and arrangement of appropriate services. Careful discharge planning can reduce the anxiety many families experience as they transition home. In general, patients are required to remain in close proximity to the transplant center for the first 100 days after allogeneic transplant. Autologous transplant patients may be referred back to their primary physician once engraftment occurs and the risk for HSCT complications has decreased.[92]

Ambulatory Care and Acute Outpatient Follow-Up. After discharge from the hospital, outpatient care usually requires a combination of clinic and home care services. Some institutions provide housing close to the main hospital to allow for close supervision of the patient's status. Maintaining a consistent team of caregivers and good communication with the patient and family helps promote posttransplant recovery and minimizes toxicities and complications. HSCT patients continue to require treatment and close observation and may need to visit the oncology clinic as often as 5 days a week for the first few weeks. Outpatient nurses regularly assess the patient's physical status, administer prescribed treatment, and manage symptoms, particularly those associated with graft-versus-host disease and toxicities.

Clinical Trials

With approximately 60% of patients diagnosed with cancer younger than 29 years of age enrolling in clinical trials compared with less than 5% of adults with cancer, clinical trials are crucial to the treatment of children with cancer.[93] Most children receiving treatment today are either enrolled in a clinical trial or receiving therapy based on the findings of a previous clinical trial.

Permission to participate in a clinical trial must be obtained. If the patient is younger than the age of 18, permission must be granted by the patient's parent or guardian; however, many health care providers involved in treating young people believe that the child or adolescent should play a role in the decision to enter a research study, and they urge investigators to share information about the study with the child and obtain his or her assent or agreement to participate.[94,95] The National Commission for Protection of Human Subjects of Biomedical and Behavioral Research established age 7 as a reasonable minimum age for involving children in some kind of assent process.[94] After consenting to participate in a clinical trial, the child and family may have lingering questions about the study and turn to their nurse for clarification and more information. The nurse may arrange for them to meet again with the consenting physician to ensure that all questions have been addressed and that their decision to participate is truly informed.[95]

Once a patient has enrolled in a clinical trial, the research coordinator assigned to the trial, in partnership with the primary team, ensures that all required studies have been completed and that consent forms have been signed. Throughout the course of a trial, nurses help to oversee and maintain compliance with the study's protocol, provide ongoing staff education, and are primary collectors of the data used for dose adjustments and analyses. Nurses adhere to the principles of good clinical practices, including adequate human subject protection as a critical requirement to conducting research involving human subjects.[96] The role of the clinical research nurse includes, but is not limited to, administering investigational drugs; monitoring the patient's responses; assessing patient for adverse side effects in accordance with protocol criteria; collecting timed specimens according to the protocol schedule; and carefully documenting the start and stop times of drug administration.[97] Nurses also provide essential patient and family education and support, checking in with them frequently and bringing unresolved concerns to the attention of the team.[97,98]

Complementary and Alternative Medicine (Integrative Therapies)

It is not uncommon for a family whose child has been diagnosed with cancer to explore complementary and alternative medicine (CAM) at some point during the treatment process. CAM, also referred to as integrative therapies, includes practices and therapies that lie outside the realm of traditional medicine. They encompass a wide variety of approaches, including acupuncture, massage, imagery, energy healing, and prayer, as well as herbal, homeopathic, nutritional, and biologic therapies.[99] Although evidence that CAM improves immunity or promotes recovery is not well documented, the use of CAM among children and adolescents with cancer reportedly ranges between 46% and 85%.[100-102]

Even though CAM is not a replacement for standard pediatric oncology treatment, many patients and families view it as a form of adjunctive therapy that may be used to help relieve symptoms, cope with life-threatening illness, and improve well-being.[103] While working with a patient and family, pediatric oncology nurses and other providers should routinely assess whether the patient has used CAM. During all medication reviews, the patient and family should be asked to list any herbs and supplements the patient is taking. Although obtaining this information is an important part of the medication review process, many families report never having been asked about such practices.[103]

Patients often turn to nurses for information and insight about available therapies that might be useful to them. When trying to determine the best therapy for the patient, consideration should be given to the family's culture, spiritual beliefs, and practices and the patient's developmental level, education, and preferences.[99,104] Nurses' observations and documentation of a patient's response to CAM treatments are essential because they help providers gauge the impact of the treatments, as well as their potential interactions with individual therapies, and provide insight into the patient's coping strategies.

Symptom Management and Supportive Nursing Care

The advanced, complex treatment regimens designed to cure childhood cancer commonly produce multiple distressing side effects. Each treatment modality carries the potential for side effects that can occur during treatment or days, weeks, or even years after treatment. Side effects such as hair loss and low blood cell counts may be transient, whereas others, such as hearing loss and learning disabilities, can be permanent.[77,105] The most commonly reported side effects in children and adolescents with cancer include infection, bleeding, anemia, nutritional problems, nausea, vomiting, mucositis, fatigue, and pain.[61] Studies have found that children report nausea, fatigue, and pain as the most distressing.[106,107] Although many side effects can be effectively managed, some families believe suffering is to be expected among children with cancer. As a result, side effects may go unreported for a time and children may suffer unnecessary distress.[108,109]

Nurses help manage the side effects of cancer treatment by using strategies that have been tested and proven effective through research and evidence.[105] The nurse continually evaluates the effectiveness of symptom management strategies and, when necessary, collaborates with the interdisciplinary team to revise the plan so that it matches the needs and experiences of the individual patient. The following section summarizes specific nursing interventions associated with some of the most common and troubling side effects encountered in children with cancer.

Myelosuppression

Myelosuppression is a condition in which bone marrow activity is decreased, resulting in fewer red blood cells, white blood cells, and platelets.[110] It is the most common toxicity associated with radiation and many chemotherapeutic agents.[105] It can also occur with certain malignancies, such as leukemia, sarcoma, neuroblastoma, and lymphoma.[61] Patients receiving myelosuppressive agents commonly experience a nadir between 10 and 14 days after the end of treatment. With subsequent courses of myelosuppressive agents, the nadir and recovery from the nadir can be affected by the number and type of agents given and the timing of their administration.[105,111] Pediatric oncology nurses monitor a patient's response to treatment over time and anticipate complications of myelosuppression, such as infection, bleeding, and fatigue. Educating families to be aware of the signs and symptoms associated with complications related to myelosuppression, as well as when to report these symptoms, is an important part of the overall care of patients receiving cancer treatment.

Neutropenia

Neutropenia is characterized by an absolute neutrophil count of 1000 per mm^3 or less.[77] It is the most severe consequence of bone marrow suppression, increasing a patient's risk for potentially life-threatening infections, a risk that is higher when neutropenia is prolonged for more than 7 days. When neutropenia presents as fever, it must be treated as an emergency with broad-spectrum antibiotics administered as soon as possible.[112] The neutropenic patient often does not present with the routine signs of infection. In many cases, fever may be the only presenting symptom.[113,114]

Hand washing before and after contact with each patient minimizes the risk for microbial transmission and is the single most important method for preventing nosocomial infection.[115-117] BRMs can also help lower a patient's risk for infection by shortening the period of myelosuppression. These agents are usually given 24 hours after chemotherapy administration as a one-time subcutaneous injection or daily by the nurse, patient, or family member until the white blood cell count recovers.[118,119] Because many children associate subcutaneous injections with pain and fear, nurses use creative techniques and special devices to ameliorate the discomfort associated with these injections.

Major pathogens that cause infections in the neutropenic patients are bacteria, fungi, viruses, and protozoa, with gram-negative bacterial infections associated with higher mortality rates than all other causes of infection.[112] The administration of prophylactic antibiotics to prevent *Pneumocystis jiroveci* (formerly known as *Pneumocystis carinii*) pneumonia, a protozoal infection found in patients with prolonged neutropenia, is also a standard practice in many cancer treatment protocols.[120,121] These antibiotics are usually administered in an oral form and are commonly given throughout treatment. Getting children to take daily oral medications can be very distressing for parents of young children and adolescents. Teaching parents techniques that will help them to administer medications successfully and emphasizing the importance of the medications enhances the parents' ability to cope and has the potential to increase overall compliance with prescribed medication regimens.

Educating the patient and family about neutropenia is critically important. Elements of this education must include the meaning of blood cell counts, signs and symptoms of infection, an understanding that the time of greatest risk for infection occurs during nadir, and strategies to minimize the risk for infection (Box 69-4).[122,123] Because the family plays an important role in monitoring a patient for signs of infection, nurses also focus on teaching them when to contact the child's provider. Family members are taught how to take a temperature and that the presence of a fever may signal an emergency; they are instructed to call the provider whenever the child's temperature is higher than 38° C (100.4° F) on two occasions within 24 hours and to call immediately whenever it is higher than 38.5° C (101.3° F) (or per institutional guidelines). They are also taught to report any respiratory symptoms, shaking chills, and changes in the child's level of consciousness and are instructed not to administer acetaminophen unless directed to do so by the provider. In addition to reviewing these instructions regularly, nurses make sure family members have emergency contact information. Families must be taught the critical nature of fever and neutropenia and the importance of initiating antibiotics rapidly.

Early assessment and intervention are key to successfully managing a febrile neutropenic patient.[105] Whenever a fever is present, blood cultures are obtained from central venous access devices and peripheral sources. Broad-spectrum antibiotics are usually started within 60 minutes of the diagnosis of fever and neutropenia.[124] Treatment

Box 69-4 **Neutropenic Precautions: Guidelines for Patients and Families**

- Notify the physician if the child exhibits any of the following:
    - Oral or axillary temperature is ≥38.5°C (101.3°F) or is 38°(100.4°F)C two times within 24 hours
    - Oral lesions
    - Erythema at central venous access site
    - Open skin lesions
    - Perirectal laceration or irritation
    - Cough
    - Rhinorrhea
    - Tachypnea
    - Complaints of ear or throat pain
    - Diarrhea
    - Lethargy
- Perform meticulous hand washing.
- Do not take rectal temperatures or give suppositories.
- Avoid crowds and people who are sick.
- Do not share utensils with others.
- Do not let the child provide direct care to pets (e.g., the child should not change kitty litter).
- Do not keep reptiles or birds as pets.
- The child and siblings should not receive live-virus vaccines.
- Avoid exposure to mold (e.g., digging in soil).
- Practice good mouth care.

Data from references 122 and 123.

may be modified once the results of the culture and sensitivity are available and the specific organism has been identified. Antifungal therapy is often added if the patient's fever persists despite antibiotic treatment.

Most patients with fever and neutropenia are admitted to the hospital for treatment. During this time, nurses observe patients closely for signs and symptoms of septic shock by monitoring vital signs, peripheral perfusion, and intake and output. The patient's neurologic status is also monitored closely because lethargy, irritability, or a change in consciousness can indicate sepsis. Mouth care and perianal hygiene are performed on a routine basis. Rectal temperatures and suppositories are avoided in all neutropenic patients based on the risk for tearing the anal mucosa and introducing bacteria.

Anemia

Anemia can occur secondary to myelosuppression after chemotherapy or radiation therapy, most commonly appearing 7 to 10 days after treatment. It can also occur as a result of blood loss, metastasis to the bone marrow, or viral suppression.[105] Nurses routinely monitor all patients for symptoms of anemia, watching for pallor (particularly of the lips and conjunctiva), fatigue, tachycardia, gallop rhythm, headache, dizziness, dyspnea on exertion, and irritability.

Many children exhibit a high tolerance for low hemoglobin levels. Transfusions, however, are commonly necessary when the patient is symptomatic, hemoglobin is less than 7 g/dL, and the hematocrit is less than 21%. Recombinant human erythropoietin may be used to increase red cell recovery and decrease the need for transfusions, especially when the patient and family object to blood transfusions on the basis of religious beliefs. It takes erythropoietin 2 to 4 weeks to stimulate red cell precursors, whereas the effects of a transfusion are immediate.[118] Transfusion amounts are generally in the range of 10 to 20 mL/kg. Red blood cells should be leukoreduced to decrease alloimmunization and irradiated to inactivate T cells and reduce the risk for graft-versus-host reactions.[125]

Because the patient and family are often the first to note symptoms of anemia, the nurse focuses patient and family education on anemia, its symptoms, when it is most likely to occur, and how to manage symptoms at home, such as providing frequent rest periods. If a transfusion is ordered, nurses follow a standardized protocol to ensure that the blood product is administered safely and monitor the patient frequently for fever, chills, body aches, urticaria, pruritus, wheezing, respiratory distress, and other signs of reaction to transfusion.[105,126,127] Prior to the transfusion, a patient may require premedications to prevent transfusion reactions. Once the transfusion is complete, the nurse documents the patient's tolerance of the transfusion and whether premedications were administered. This information is important to guide future transfusions.

Thrombocytopenia

Thrombocytopenia, or a platelet count of less than 100,000/mm^3, can be caused by myelosuppressive therapy, disease, or coagulopathy.[127] Thrombocytopenic patients are at risk for internal bleeding when the platelet count falls below 15,000 to 20,000/mm^3.[127,128] Nurses instruct the patient and family in strategies for preventing injury, hence minimizing the chances that bleeding will occur (Box 69-5).[129] Nurses regularly assess a thrombocytopenic patient's risk for bleeding and communicate any

Box 69-5 **Bleeding Precautions (Platelet Count <20,000/mm^3): Guidelines for Patients and Families**

- Notify the physician if the child exhibits any of the following:
    - Increased bruising
    - Evidence of bleeding
    - If a nosebleed occurs, pinch the nostrils together for at least 10 minutes. (Use gauze to pinch the nostrils, holding it between your thumb and forefinger.) Go to the emergency department if the bleeding persists after this time.
    - Change in level of consciousness
- Whenever the platelet level drops below 50,000/mm^3, avoid skateboarding, trampolines, contact sports, and other activities that can cause bleeding.
- Always wear a helmet when riding a bicycle.
- Shave only with an electric razor.
- Clean teeth with a soft toothbrush or gauze. Do not use dental floss.
- Avoid sharp foods such as tortillas that can cause gum injury and bleeding.
- Avoid aspirin, aspirin products, and ibuprofen.
- To prevent straining, keep stools soft using prescribed laxatives and stool softeners.
- Avoid taking rectal temperature, enemas, and suppositories.
- Oral contraceptives may be prescribed to prevent excess bleeding during menses.
- Avoid sexual intercourse.

Modified from Elliott S: Thrombocytopenia. In Kline N, Brace-O'Neill J, Hooke M, et al, editors: Essentials of pediatric oncology nursing: a core curriculum, *2nd ed. Chicago, 2004, Association of Pediatric Oncology Nurses, p. 69–70.*

pertinent laboratory findings or symptoms to the clinical team. Platelets are commonly administered when patients are symptomatic, if below 50,000/mm^3 and scheduled for a lumbar puncture, or in accordance with institutional or protocol guidelines. Patients receiving platelets are monitored carefully during and after the transfusion for signs of transfusion reaction.[125,127,128]

Fatigue

Fatigue is a major side effect of cancer treatment in children and adolescents.[130-132] Although defining fatigue in children undergoing cancer treatment has been challenging, children and adolescents can reliably describe the physical and mental symptoms associated with fatigue. Nurses routinely assess for fatigue throughout the course of treatment to determine possible factors that may contribute to fatigue, such as nutritional problems, pain, dehydration, and patterns of activity.[130,131] While caring for patients, nurses incorporate interventions designed to minimize fatigue. For example, with hospitalized children, incorporating adequate sleep time into the plan for the day and minimizing noise during sleep hours can sometimes be effective. In outpatient settings, nurses work with other members of the care team to avoid long waiting times to conserve and maximize energy, ensure adequate time for rest, and work with patients and families to optimize the patient's nutritional status. Other interventions and treatments that may decrease fatigue include pharmacologic assistance, physical activity, and distraction techniques. Integrative therapies that promote well-being and relaxation, such as massage and Reiki therapy, are increasingly employed in symptom management and show promise for relieving fatigue and promoting well-being.[99,103,104]

Nausea and Vomiting

Nausea and vomiting are common side effects of cancer treatment and described by patients as the second most distressing symptom after fatigue.[106] Uncontrolled vomiting can produce its own complications because it may quickly lead to dehydration and electrolyte imbalance. In some cases, nausea and vomiting can become dose-limiting side effects of chemotherapy if resolution requires a delay in treatment or a reduction in the chemotherapy dose.[76,105]

For a patient just beginning chemotherapy, the first cycle offers predictors of the chemotherapy's emetogenic potential. Antiemetics are typically ordered on the basis of symptoms observed during and after the cycle and adjusted according to the patient's response to subsequent cycles. The antiemetic regimen can also be adjusted to accommodate escalating doses of chemotherapy, as well as to manage breakthrough nausea and vomiting. Other interventions that may benefit some patients include antispasmodic therapy, relaxation techniques, acupuncture, and guided imagery.

Nurses routinely assess patients for nausea and vomiting during each chemotherapy cycle, obtaining information that helps in establishing and evaluating the effectiveness of the antiemetic regimen. They often encourage patients and families to maintain a diary describing the response to the antiemetic treatment and to list management strategies that the patient finds effective. Such information can help providers fine-tune the antiemetic regimen to the individual patient. When teaching patients and families about the regimen, nurses stress the importance of continuing antiemetics for the prescribed length of time.

Mucositis

Mucositis, or damage to the gastrointestinal cells and ulcerations of the mucosa, can develop as a result of chemotherapy or radiation therapy.[133] Ulcers that occur in the mouth are a dose-limiting toxicity that affects quality of life. Painful mouth ulcers make it difficult to eat and drink and can compromise a patient's nutritional status.[134,135]

Before treatment begins, patients are instructed to obtain dental care to ensure good oral hygiene and integrity. If applicable, they are usually asked to have their braces removed to decrease the potential for infection and gum irritation. Once treatment starts, nurses work closely with patients and families to ensure adequate oral hygiene and decrease the risk for mucositis. Upon meeting with patients and their families, nurses assess the patient's oral cavity and their baseline oral hygiene habits. The nurse instructs them in the techniques of good oral care, including rinsing the mouth frequently with water using a saline solution and a soft toothbrush or gauze to clean the teeth and gums three to four times a day.[105,136,137] Nurses also assess patients for mouth pain and discomfort and work with the care team to alleviate pain and promote adequate nutrition.

A wide variety of agents are marketed for the treatment and prevention of mucositis. Recent studies have shown that cold substances administered to the oral mucosa during chemotherapy administration (e.g., having patients suck on flavored ice popsicles) can help prevent mucosal cell damage.[133]

Pain

Pain is a common and distressing side effect of pediatric cancer and cancer treatment. Although techniques for managing pain effectively in children and adolescents are widely available, patients with cancer still experience unnecessary suffering. Inadequate pain assessment and poor communication between patients and providers are just two of the barriers to successful pain management. Other obstacles include lack of knowledge by health care providers about the manifestations of pain in pediatric patients and about how it is best managed. Taking the time to assess patients regularly to determine the type, cause, location, and intensity of pain will assist in developing an individualized management plan to relieve pain and optimize quality of life.

The use of a procedure room should be considered for hospitalized patients undergoing painful procedures in an effort to preserve the bed as a safe place. In addition, limiting the number of attempts by a single health care provider is one technique used to minimize discomfort. Whereas institution-specific procedures may define the process for managing multiple unsuccessful attempts by

Box 69-6 **Common Myths and Barriers to Effective Pain Management in Children**

ASSESSMENT

A child reports pain to the nurse or doctor.
If a child does not complain of pain, the child is not suffering.
It is always possible to determine whether a child is faking pain or truly suffering.
Active or sleeping children cannot be in pain.
Pain must have an evident stimulus; without one, a child cannot be feeling pain.
If a child is in pain, the parent would know it.

DIAGNOSIS

Infants have immature nervous systems and therefore feel less pain.
Children do not remember painful events.
Children become accustomed to pain and no longer feel it.
Children cannot communicate the location and intensity of pain.
Neurologically impaired children do not feel pain.
Adolescents are drug seekers.

PAIN MANAGEMENT

It is unsafe to administer opioids to children because of respiratory depression and addiction.
The best way to give an analgesic is intramuscularly.
It is unsafe to give narcotics through a central line.
Administering morphine means the patient is dying.

Modified from Jodarski K, Wilson K: Pain. In Kline NE, Brace-O'Neill J, Hooke MC, et al, editors: Essentials of pediatric oncology nursing: a core curriculum, *2nd ed. Glenview, IL, 2004, Association of Pediatric Oncology Nurses, p. 155.*

one provider, if not otherwise specified it is recommended that a provider seek the assistance of another provider after three unsuccessful attempts.

Over the past decade, providers have become more aware of and concerned about pain in children, and efforts to understand and manage all aspects of pain have resulted in an overall improvement in pain management.[68,138] The creation of dedicated teams of clinicians who specialize in the treatment of pain has also contributed to the introduction of new drug combinations and techniques for the treatment and control of pain.[139]

Assessing Pain and Developing a Pain Management Plan. For pain to be effectively managed, dispelling the myths that exist regarding pain in children is important (Box 69-6) because believing any one of them can markedly compromise efforts to manage a patient's pain.[67,140] Although the most accurate and reliable indicator of pain remains the patient's report, many children cannot or do not consistently and independently report pain. Therefore health care providers must consider the physiologic and psychological components of pain and develop techniques for routine assessment.[67,68]

Finding the most effective pain management strategy begins with assessment. Nurses conduct routine pain assessments incorporating an understanding of the common types of pain and an appreciation of how pain is manifested by children at varying developmental stages. Because pain can affect patients differently, a comprehensive assessment typically includes the patient's pain threshold, fears related to particular drugs, cultural beliefs, anxiety level concerning pain control and, in adolescents and young adults, past use of alcohol or illicit drugs. A key component of the assessment also involves measuring the intensity of pain with an appropriate instrument. The most common scales use faces or numbers to gauge a patient's pain level. Scales that incorporate faces are particularly helpful in pediatrics because they can be understood by a variety of age groups and by patients who do not speak English.[141] Numerical scales, which generally ask the patient to rate pain on a scale of 1 to 10, are appropriate for children 5 years of age and older.[67,140,142]

Managing Pain and Stress during Invasive Procedures. Cancer treatment often involves numerous invasive procedures, such as bone marrow aspirations and lumbar punctures. Children with cancer perceive these procedures as extremely painful[143] and often report years later that the procedures were the most frightening and traumatic part of their cancer care.[134,144,145] Studies have demonstrated that children do not adapt to procedure-related pain; instead, the trauma and anxiety associated with procedures increases with repeated painful experiences.[61,143,146]

The pain and stress involved in procedures is commonly underestimated. Providers who believe that a procedure is brief and that sedation is time consuming may fail to manage procedural pain and anxiety with adequate attention. Offering support and preventing pain during procedures is the responsibility of nurses and physicians. A preprocedure assessment is usually conducted to determine the approach that is best suited to each particular patient.

Properly preparing a child to prevent trauma during the first procedure has been shown to have a direct impact on the ability of the child or adolescent to tolerate and cope with subsequent procedures.[134] A patient optimally managed through a combination of pain medication, careful timing, and parental support seems to be less anxious about and fearful of successive procedures.[142] A child who has had traumatic experiences during procedures in the past may demonstrate such symptoms as insomnia, anxiety, regression, and depression as the time for another procedure approaches.[61,140,145,146] If these symptoms do appear, providers should question whether past efforts to prevent or control pain have been adequate.

Researchers continue to build evidence for the best way to prepare a child for invasive procedures. Studies support general anesthesia as a safe and effective method of pain control and psychological support because procedural anesthesia does not require intubation and is accomplished quickly and effectively through the use of short-acting intravenous anesthetic agents.[143,147] If anesthesia services are not available, procedural sedation is recommended. Procedural sedation involves various pharmacologic combinations, most commonly an opioid analgesic such as fentanyl and a benzodiazepine such as midazolam, for anxiolysis and sedation.[142,144] Used in combination, these agents depress the level of consciousness while still allowing the child to maintain his or her airway independently and to respond to physical stimulation or verbal command. Carefully administering agents before and during the procedure can ensure a pain-free experience for children and adolescents.

A patient scheduled to receive general anesthesia or procedural sedation is ordered to have nothing to eat or drink for 6 to 8 hours before the scheduled procedure. An infant may have breast milk for up to 4 hours before and clear liquids until 2 hours before sedation. Ideally, the withholding of food and fluids begins at night and the procedure is performed early the following day to limit the child's distress. The nurse assisting with the procedure prepares the procedure room, ensuring that all necessary equipment such as oxygen saturation and cardiac monitor is available. For procedures performed with the patient under general anesthesia, the anesthesiologist ascertains that all the necessary anesthesia and emergency equipment is available, administers anesthetic agents, and monitors the patient. When procedural conscious sedation is used, the patient's physician or nurse practitioner usually determines the time of the procedure and prescribes the sedative agents to be used. The nurse assisting with the procedure initiates the time out, administers the prescribed sedative agents, and may also administer antiemetics if intrathecal chemotherapy is being given. During a procedure, the nurse carefully monitors vital signs and oxygenation. A pulse and oxygen saturation monitor is generally used throughout the procedure and for at least 30 minutes during the recovery period or until the patient's values return to baseline.[68,144]

For less invasive procedures, the application of a local anesthetic cream to the procedure site several hours before the procedure has been found to reduce pain. Applied in a thick layer (2 mm) and covered by an occlusive dressing that is left undisturbed for an hour, the anesthetic cream penetrates the skin and provides local anesthesia up to a depth of 5 mm for 2 to 3 hours. Anesthetic creams have been found to reduce the pain associated with a range of procedures, including venipuncture, lumbar puncture, injection, and accessing indwelling central venous lines.[148,149] In an ambulatory setting, a nurse may teach the parents to apply the cream before leaving home so it is at peak effectiveness on arrival at the hospital. The cream's effectiveness may be decreased by poor hydration and dark skin pigmentation and offers limited effectiveness in controlling the pain of bone marrow aspiration, which requires the addition of locally injected lidocaine and procedural sedation or anesthesia.

Stress Reduction Techniques. A child often benefits from having parents with them during a procedure. This is particularly true for toddlers and preschoolers for whom separation anxiety is a developmental issue. During the procedure, the parents should be positioned close to the child so they can offer reassurance and comfort and help the child use stress reduction and coping techniques. A parent who is uncomfortable staying with the child should be supported in that decision and given reassurance that the child will be well cared for and that a member of the team, such as a child life specialist or a member of the psychosocial staff, will be available to offer the child support.

A variety of behavioral techniques, such as music therapy, distraction, and relaxation methods, can be useful in reducing anxiety and managing the pain associated with cancer treatment and invasive procedures. Nurses routinely work with other members of the care team to identify techniques appropriate for the patient and to help the patient and family learn and use the techniques during treatment.[150] The appropriate stress-reduction techniques for a particular child are determined in part by the child's developmental age and individual preferences. An infant, for example, may benefit from sucking on a pacifier or sucrose nipple, whereas a toddler may be distracted by a book, a tactile toy, or music. Guided imagery often works well with a child of school age or older; an adolescent may prefer being distracted by a CD player with headphones or a video game. Medical play may also be used to help relieve a child's anxiety. Introduced before a procedure is performed, it allows the child to perform the procedure on a doll and to ask questions and examine equipment that will be used. Such play allows a child to gain insight into and understanding of the procedure and the sensations he or she will experience.[47,140]

Central Venous Catheters

Central venous catheters (CVCs) are one of the most important advances in the treatment and supportive care of children with cancer. The most commonly used CVCs are peripherally inserted central venous catheters, tunneled central venous lines, and implantable reservoirs inserted under the skin, also known as portacaths. Today, a CVC is considered integral to managing patient care; minimizing discomfort caused by placement of peripheral intravenous lines; and ensuring safe administration of blood products, parenteral nutrition, chemotherapy, antibiotics, and antifungal and other agents. CVCs can also be used to obtain blood samples and perform infusions in the patient's home.[149]

Complications associated with CVCs include local and systemic infections, central line–associated bloodstream infections (CLABSIs), septic thrombophlebitis, and endocarditis.[115] Other potential complications include bleeding, thrombus formation, and catheter damage or dislodgment. The complications can be significant, but the benefits of using CVCs generally outweigh the risks. To minimize and prevent complications, meticulous care of the CVC is required. Maintenance of a CVC requires special care to reduce the risk for infections. Extensive staff, patient, and family education must be conducted to ensure consistent and effective care of the CVC and the ability to identify the signs and symptoms of infection. To prevent the possibility of a nosocomial infection, caring for a patient with a CVC requires training in proper aseptic technique and good hand washing. In recent years, some institutions have found that a 15-second wipe of the cap prior to the entering line is the minimum necessary to remove bacteria. Guidelines developed by the manufacturer or institution-specific policies and procedures are designed to minimize the risk for infection and should be followed whenever a CVC is accessed.[117,121]

One of the most common complications in a CVC is a CLASBI. If a CLASBI is suspected, blood cultures are drawn immediately and antibiotic therapy is started. The administration of antibiotics for treatment of the infection should be alternated between the catheter's lumens, so that each lumen of a double- or triple-lumen catheter is used and the risk for colonizing an unused lumen is minimized. Depending on the institution's guidelines, the CVC may be removed, particularly if the patient has positive blood cultures 72 hours after antibiotics are initiated, evidence of tunnel infection, catheter-related septic shock, or occlusion of catheter that cannot be cleared by thrombolytic or chemical treatments.[124] If the CVC is not removed, parenteral antibiotic therapy usually continues for 7 to 10 days after a first negative blood culture is obtained in a patient who is not immunocompromised and for 10 to 14 days in an immunocompromised patient.[151,152]

Reduction of CLABSIs has become a national priority as well as an institutional one for many centers. CLABSIs are defined by the Centers for Disease Control and Prevention (CDC)/National Healthcare Safety Network (NHSN) and are a source of morbidity, mortality and increased medical costs.[153] The NHSN, established by the CDC, reported that in 2004 the mean among 54 pediatric intensive care units (PICUs) was 6.6 bloodstream infections per 1000 catheter-days, higher than many adult centers.[153] Recognizing the impact CLABSIs have on patients, families and institutions as well as in an effort to reduce infections, the National Association of Children's Hospitals and Related Institutions (NACHRI) partnered with clinical providers on a quality improvement initiative to examine bloodstream catheter infections in its (PICUs. Small tests of change were implemented and identified best practice, which included insertion and maintenance care bundles. Changes implemented resulted in a decrease of bloodstream infections from 5.40 per 1000 catheter-days to 3.10 per 1000 catheter-days. After 1 year the NACHRI PICU collaborative achieved a 43% reduction in catheter-associated bloodstream infection rates.[153] To date, pediatric oncology centers throughout the country are participating in a separate NACHRI collaborative specific to hematology, oncology, and stem cell transplant patients, with the goal of reducing bloodstream infections. Critical to prevention of CVC infections is focused education and training. Adherence to best practice and maintenance of the CVC, performance improvement plans, and nurse staffing are critical in prevention efforts to reduce bloodstream infections.[154]

Although a CVC is typically cared for by the nurse while a patient is in the hospital or clinic, the patient and family assume that responsibility at home. Patient and family education related to using and caring for the line at home is an important part of nursing care. Teaching begins before the line is inserted and covers a range of topics, such as proper technique for CVC dressing changes, how to flush the line with saline and heparin safely, and how to recognize the signs and symptoms of complications. Education of the patient and family consists of a series of demonstrations by the nurse of all procedures necessary to care for the CVC, followed by return-demonstrations by the parents. During the return-demonstration the nurse is able to evaluate technique and identify areas that need additional review. Other teaching materials, such as books and teaching dolls, may also be used. In addition to the management of the CVC, the patient and family are taught to identify the signs and symptoms of infection and to report untoward findings to the physician immediately. Family members are instructed to avoid giving antipyretics unless directed by the provider.

A patient with a CVC is also referred to a home care nursing service that provides nursing support and instruction in the child's home. The child's inpatient or clinic nurse works in collaboration with the home care agency to ensure that the supplies needed to care for the CVC and any prescribed medications are delivered to the patient's home.

Caring for Patients Across Multiple Treatment Locations

For many pediatric cancer patients, treatment spans months or years and takes place in multiple settings. Much of a patient's care is delivered through an ambulatory clinic, but many patients are hospitalized from time to time and also receive care from home care providers. Coordinating care across multiple sites and providers presents a complex challenge for the pediatric oncology care team as well as for the patient and family. Good communication, clear documentation, and careful planning are essential to safe and seamless care. Before a patient leaves a setting, the care team must develop a transition plan to ensure that the patient and family, as well as the team receiving the patient, are well informed about the patient's needs and treatment. In addition, nurses or social workers serving as case managers or care coordinators work with the primary care team to arrange for community services and obtain insurance approval for services and equipment the patient will need.[49,155]

Nursing agencies and other organizations in the community are often called on to help with a patient's care in the home. Some pediatric oncology patients may require home care nursing to assist with central line care, hyperalimentation, chemotherapy or antibiotic therapy, pain management, and psychological support. A home infusion company may also be involved to provide line care, infusion supplies, and pumps.

Although most patients receive the majority of their chemotherapy in an ambulatory clinic, some patients and families choose to administer chemotherapy at home, with the support of a home chemotherapy and infusion service. Research has shown that such home treatment programs are associated with lower total costs and yield no significant differences in patient outcomes.[156-158] Patients and families have noted that these programs not only help to decrease disruptions to their daily lives but also help reduce psychological distress.[159]

Whenever home care nurses or other community-based services are brought into a patient's home, the primary nurse from the inpatient or ambulatory setting should speak with the home care provider to provide a detailed patient history and outline specific home care needs. Written communication detailing specific flushing orders, cap changes, protocols, blood sampling, and when to call the doctor should also be provided. Once the patient is home, communication between the home care agency and the patient's providers must continue to ensure that the treatment plan is carried out appropriately and that the home care nurses know when and whom to call if they have questions or concerns.

PHARMACEUTICAL ADVANCES

Emerging Therapies

Advances in molecular biology and translational research will eventually allow selective targeting of tumor cells and radically change the way children with cancer are treated. Investigators who identify the underlying biology, potential obstacles to delivering the therapy, and the possible impact of new therapies on the practice of pediatric oncology will be preparing for the future of pediatric oncology. In recent years, treatment of genetically defined cancers—those cancers known to harbor specific genetic abnormalities—has moved away from general cytoxic chemotherapies toward agents that specifically target proteins and signaling pathways that cancer cells need for their growth. Called targeted therapies, these agents can induce dramatic clinical responses and offer significant therapeutic benefits in treating many previously hard-to-treat cancers, including certain melanomas, colorectal cancers, thyroid cancers, and advanced lung cancers.[160] As these therapies start to become available in clinical trials for children, pediatric oncology nurses will have to be educated regarding the agents, administration, adverse reactions, and side effects.

Patient Safety Considerations

Advances in the delivery of cancer therapies have reduced the risk for medication errors and improved patient safety. One of the most technologically advanced methods of reducing medication errors has been attributed to barcoding medication administration (BCMA). Until recently, general initiatives in place to reduce medication errors were limited to an institutional awareness of safety, examining the processes around medication administration to identify sources of error, and reviewing medication events. The advent of barcoding brought with it the ability of the nurse to verify the identification of the patient and prescribed medication via technology and thus not having to rely only on visually checking the medicine and patient to confirm that the "five rights" (right patient, drug, dose, route, and time) are correct. The literature has reported significant reductions in medication administration errors, from 50% to 90%, comparing retrospective data prior to BCMA with adverse event reporting after implementation and potential errors avoided.[75] One estimate is that BCMA may prevent more than 84,000 medication errors in the United States.[161]

SUPPORTING PATIENTS AND FAMILIES AT THE END OF TREATMENT

Usually, the patient and family eagerly await the completion of treatment. Its arrival, however, may be accompanied by uncertainty and fear. For some patients and families, ending treatment means a departure from the relative security of routine visits to the oncologist and signals a return to their pre-cancer world. This transition is typically accompanied by a whole host of worries about their child's future and the potential for recurrence. Some of the anxieties troubling a patient and family stem from the fear that once the cancer is no longer actively battled, the child will become more vulnerable to illness or disease. This anxiety is often heightened by the gradual loss of contact with the health care team as providers pay more attention to "sick families" and by the loss of the psychosocial support that the team has long provided.[21,162-164] Helping the patient and family transition from active treatment is an important part of comprehensive cancer care. The primary oncologist and nurse or nurse practitioner play key roles in this process because they provide much of the guidance and information that the patient and family need to transition from treatment successfully.[162,165]

The Emotional Impact of Transitioning from Treatment

For the patient and family, leaving the safety net provided by the health care team means they must adapt to living with the uncertainties of surviving cancer while reestablishing the life they had before cancer was diagnosed.[163-165] Often a patient finds it difficult to reassume the role of a well person and to integrate back into the contexts of family, school, and community.[163,164] Although the literature suggests that most childhood cancer survivors do relatively well from an emotional perspective, studies indicate that some survivors and their parents can exhibit trauma-related symptomatology and experience ongoing worry and alienation. For many survivors and families, the impact of the cancer experience stays with them long after treatment is over.[166-168]

The context of posttraumatic stress can help clinicians understand the long-term psychological reactions of the survivor and family.[168] The end of treatment may signal a return to normalcy from the providers' perspective, but it can hold a very different meaning for the patient and family. An individual's ability to reintegrate into the community and adjust to a "new normal" as a cancer survivor can be impacted by the psychological sequelae that result from prolonged uncertainty; the emotions, ranging from joy to unspeakable sadness; the restrictions the patient and family must still observe; and the extra work and overall loss associated with the cancer experience.[164,167]

Supporting the Transition

Patients' descriptions of their experiences after cancer treatment suggest that they and their families often need help in accepting and dealing with their new situations and circumstances.[162,163] Before providers can help patients and families, however, they must first understand the psychosocial impact of childhood cancer, as well as the heightened fears and the intense need for reassurance that families experience once treatment is over. These needs and fears may be especially evident when the child experiences common illnesses or during follow-up procedures and appointments.[21,165,166]

Nurses, physicians, and other providers can help to alleviate the fears of patients and families by validating the psychological distress that may surface at the end of treatment, by answering all questions, by providing honest feedback, and by helping them to begin to trust their ability to adjust to life after treatment.[41,164] Additional strategies include providing patients and families with ample opportunity to discuss concerns, acknowledging that fears of recurrence are normal, and preventing additional anxiety by ensuring that all posttreatment test results are reported to patients and families in as timely a manner as possible.[163]

The oncology team can also help to prepare patients and families for the challenges that lie ahead by teaching them about what to expect once treatment is over and by connecting them to programs that support the reintegration process. Support groups, programs that help with school reentry, camps that allow patients to socialize with other cancer survivors, and clinics that focus on cancer survival can all be instrumental in helping patients and families adjust to life after treatment.[163,169,170] Efforts to educate the patient and family and to support their transition from treatment can not only facilitate psychosocial adaptation but also improve the quality of life for cancer survivors.[165,171]

Because nurses are a primary source of support and information for patients and families, they play a critical role in ensuring a successful transition that is based on a unique understanding of the indicators of healthy transition: patient and family demonstration of an overall sense of well-being, observed mastery of skills required for home management, and well-being of the relationships among family members.[172] Nurses employ a variety of strategies to support transition after cancer treatment, which include, but are not limited to, an assessment of readiness, as well as the provision of materials and information about resources that patients can draw on once they leave the oncology setting. Information about programs and support groups for cancer survivors and written materials that outline follow-up care and potential side effects of treatment can be invaluable resources for patients and families as they leave the structure and security of the hospital and transition to other care settings.[162]

NURSING CARE OF CHILDHOOD CANCER SURVIVORS

The treatment of childhood cancer is one of the great medical success stories of the past 30 years. During this time, the cure rate for all childhood cancers has risen to 78%, resulting in a dramatic increase in the population of childhood cancer survivors.[173] Today, approximately 1 in 640 adults between the ages of 20 and 39 have a history of childhood cancer.[174] One unfortunate consequence of this success is that late effects of childhood cancer treatment are now more commonly seen, effects that can occur during childhood or many years afterward, sometimes with devastating consequences. As many as two thirds of survivors experience late effects, and as many as a fourth experience an effect that is life-threatening.[174] Among the late effects that pose risks to cancer survivors are learning disabilities, infertility, heart problems, secondary tumors, and genetic issues.[162,169]

Although systematic and consistent follow-up of childhood cancer survivors is recommended, there is no consensus about where this care should be provided, who should provide it, or the detailed components that such care should entail.[174] The appropriate time to transfer care is also controversial and is dependent on the provider, although many suggest transitioning to long-term follow-up once a child has been off therapy for 2 years.

The primary pediatric oncology team, which typically has an intense investment in the childhood cancer survivor, may be reluctant to transition care to the primary provider; however, planning for the transition is essential and should begin well before follow-up care is needed. Developing a plan that includes detailed written information about the patient's specific cancer and treatment protocol ensures that the primary provider will have the necessary information to provide appropriate follow-up care. Other necessary information includes the medications the patient received (including dosages); the radiation therapy administered (including dosages); the surgical procedures performed; and any complications of therapy that the patient experienced. The oncology team should also equip the patient with documentation describing the cancer, its treatment, and possible long-term effects. Such a document in the form of a medical passport, notebook, or other transferable records is an important reference for the patient and for follow-up providers alike.

The patient and family should begin learning about late effects and follow-up care long before the end of treatment to ensure that they have a good understanding of the information presented and have a chance to ask questions and discuss concerns. Research on survivors of childhood cancer has shown that most survivors are unfamiliar with specific details of their diseases and treatments and are unaware of their risks for late effects.[170] One study found that only 30% of childhood and adolescent cancer survivors could provide adequate histories of their diseases and treatments.[175,176]

Providing a patient and family with information not only empowers them to advocate for adequate follow-up care but also prepares them to navigate the health care system and play an active role in monitoring and managing late effects once the cancer treatment ends.[177] Pediatric oncology nurses play a critical role in preparing the patient and family for the transition to follow-up care by teaching them about the disease, its treatment, and possible physical or psychological late effects. Although being careful not to overwhelm the patient and family with too much information, nurses should also address risks specific to that patient's treatment and offer guidance about how to self-monitor for late effects.[174,176] Information about organizations that offer resources for childhood cancer survivors, such as the Candlelighters Childhood Cancer Foundation and the National Children's Cancer Society, is also helpful, as are books and other written materials that provide additional practical information.[175,178]

Follow-Up Care and Care Settings

Over the past 10 years, many oncology centers have developed childhood cancer survivor clinics that monitor patients for late effects and provide treatment to improve survival rates and quality of life.[174] Centers that belong to the Children's Oncology Group are required to offer such a service. Care in these clinics is often provided by advanced practice nurses in collaboration with one or more pediatric oncologists. The nurses are trained in oncology and have extensive knowledge about survivorship issues and follow-up guidelines. During visits, nurses evaluate the patient's growth and development and conduct comprehensive screenings for late effects associated with the patient's particular cancer or treatment.[68] They also monitor the patient for systemic toxicities resulting from the cancer drugs and therapies they received. Some follow-up clinics are multidisciplinary in structure and offer the support of specialists, such as cardiologists, endocrinologists, fertility and genetic counselors, and social workers.

Although the number of specialized follow-up clinics is growing, most pediatric cancer survivors are followed by adult primary care providers. Childhood cancer survivors can also be encountered in a variety of other practice settings, such as primary pediatric settings and adult specialty clinics. Nurses and other providers in nononcology settings often have little experience working with survivors of childhood cancer and may not know about the possible consequences of cancer treatment or what to watch for. In addition, they often have little incentive to learn about the complex care required by childhood cancer survivors because many practices see very few such patients.[171]

Goals for the follow-up care of pediatric cancer survivors include identifying, preventing, treating, and curing late effects and bridging primary and special care services through education and outreach. To help support nononcology clinicians who are caring for pediatric oncology survivors, the Children's Oncology Group has developed a comprehensive set of guidelines for detecting and managing the late effects of childhood, adolescent, and young-adult cancers.[179] These guidelines were developed in a collaborative effort between the Nursing Discipline Committee of the Children's Oncology Group and the Late Effects Committee and are designed to enhance providers' awareness of potential late effects and to standardize the follow-up care of childhood cancer survivors.[177] The guidelines are risk based and exposure related and provide specific clinical recommendations for screening and managing late effects, beginning 2 years after cancer therapy has been completed. These guidelines can be obtained at no cost and, because they are on the Internet, they are readily accessible to primary care physicians, nurses, and the public.[179] Education materials developed by nursing experts are also available and can be used along with the guidelines to enhance the process of educating patients and empower patients to become proactive participants in their long-term follow-up care.[177,179]

The care of patients followed in nononcology settings can also be augmented by regular communication with the patients' pediatric oncology providers. Documentation of the cancers and the treatments given to patients (e.g., the medical notebook and other transferable records described earlier) is also an important reference for follow-up providers. Such communication, along with continuing education for community primary care providers, helps to ensure that survivors of childhood cancer receive comprehensive care and ongoing monitoring and treatment of late effects.[162] Nurses in nononcology settings may not be aware of the guidelines for follow-up care and may not be knowledgeable about the late effects of childhood cancer. Although the guidelines of the Children's Oncology Group are helpful, additional methods of training nurses about specific interventions required by the survivor population are needed.[180,181]

Follow-Up Nursing Care

Much of the care required by pediatric cancer survivors is the same as that required by other patients. For example, studies have indicated that survivors are at risk for establishing unhealthy lifestyle behaviors.[181] Because of this, nurses should use appropriate health promotion strategies and encourage survivors to exercise and maintain a healthy weight and balanced diet, avoid smoking, protect themselves from excessive sun exposure, and keep their consumption of alcohol to acceptable limits. Nurses working with adolescents, in particular, need to clarify the risks of unhealthy behaviors and encourage them to participate actively in decisions related to their health and follow-up care. Preventive screening techniques recommended for the general population (e.g., for colon, breast, and cervical cancer) should also be observed as minimum recommended follow-up.[174]

In addition to employing standard prevention and screening measures, nurses caring for pediatric cancer survivors must also help to monitor patients for late effects of cancer treatment. One of the most disturbing late effects for children and families is neurocognitive deficits. Childhood cancer survivors who received intrathecal chemotherapy or cranial irradiation or who were treated for tumors in the central nervous system are at particular risk for this late effect and should be routinely assessed for its symptoms. Patients with neurocognitive deficits may experience psychosocial problems and may have difficulties with school performance and academic achievement.[159] Memory loss and impaired intellectual or motor function can also occur and are more common in children, particularly girls, who received treatment when they were younger than 6 to 8 years of age.[182]

Survivors who have neurocognitive deficits are often placed in special education programs or programs for the learning-disabled and tend to have lower self-esteem than their siblings.[174] Families often describe the difficulties they encounter when dealing with learning issues, cognitive deficits, attention disorders, behavior disorders, and other problems associated with late effects relating to neurocognition. It is common for these families to need preparation for and assistance in working with school systems and help in obtaining referrals to and resources for neurocognitive testing. Nurses can play key roles in helping patients and families to obtain the support they need and should educate the survivors and families about three federal laws that ensure equal access to education. The Individuals with Disabilities Education Act requires states to provide free and appropriate education to all children between the ages of 3 and 21 years. The Americans with Disabilities Act prohibits discrimination against people with actual and perceived disabilities or histories of disability. The Rehabilitation Act prohibits schools that receive federal funding from discriminating against qualified students who have a history of cancer.[174] Nurses caring for pediatric cancer survivors should also become familiar with school reentry programs and advocate for continued identification of appropriate cognitive programs to promote the success of these children.

Nurses also play roles in identifying late effects related to hormones and fertility. The potential fertility issues and options for their treatment, including sperm or egg banking, should be discussed with patients and families at the time of diagnosis. Once patients enter long-term follow-up, nurses should routinely assess and document patients' sexual development, including their histories of menses, sexual function, and Tanner scale staging, and should provide education and support to patients pursuing fertility options.

SUPPORTING PATIENTS AND FAMILIES DURING RELAPSE AND RECURRENCE

Although the cure rate for pediatric cancers has improved significantly over the past few decades, recurrence of the disease is still possible and is a source of great anxiety for patients and families. Identifying and diagnosing recurrence at an early stage is among the goals of posttreatment surveillance programs because early detection may enhance the chances of successful treatment by means of a second-line protocol.[183]

Some patients and families liken the possibility of relapse to having the sword of Damocles hanging over their heads. Many begin to express fears of relapse and uncertainty as the end of cancer therapy draws near or soon after treatment is over. For patients and families who experience actual relapse, the news can be more devastating than receiving the initial diagnosis of cancer. Nurses, physicians, and other providers working with cancer patients and their families must be aware of the fear surrounding relapse and be prepared to help patients and families manage their anxiety and cope with relapse should it occur. In addition, it is important for the nurse to understand mechanisms and the guiding framework of resilience to effectively assist the patients and families in their adjustment to relapse. Examples of resilience pathways include positive coping, hope-derived meaning, and a spiritual perspective.[184]

Helping Patients and Families Cope with Fear of Relapse

With infants and very young children, the onus of fear related to relapse is generally carried by the parents. Once children reach school age, however, they, too, can experience fear of relapse and require the support of the oncology team. Some patients and families begin to raise the possibility of relapse during conversations with providers as they approach the end of treatment, whereas others do not address it until treatment is over. The fear may persist even after children or adolescents experience 5 cancer-free years, a time limit that is generally recognized as indicating recovery. In many cases the fear of relapse is brought on or is heightened by trigger events, such as the occurrence of minor illnesses or an increase in bruising.

Because outpatient nurses encounter patients and families frequently and are commonly primary sources of support, they may be the first to notice signs suggesting that patients or families are worried about relapse and they may be the first of the oncology team to whom the patients and families speak about their concerns. In addition to sharing their observations with other members of the team, nurses may recommend that patients and families meet with the oncology team's psychologist or social worker, who can help them identify ways of coping with fears and anxieties.

While encouraging patients and family members to verbalize their fears, nurses also emphasize the importance of maintaining a positive attitude because this benefits patients and families alike. Nurses also try to assess patients' siblings because they, too, can harbor fears of relapse and must be encouraged to verbalize these fears. In many centers, nurses or other providers have developed support groups for siblings that help them to express their feelings while engaging them in various activities, such as outings, discussion groups, or arts and crafts projects that allow them to spend time with others who have shared the same experience.

Recurrence

More upsetting than the fear of relapse is the experience of an actual relapse. The fear of recurrence can have a profound effect on patients and families, but experiencing actual relapse can be devastating. How families respond to the news of relapse has marked effects on the patients' responses to the illness and on the psychosocial environments in which they must continue to grow and develop.[56] Once parents are informed of a relapse, nurses and other members of the care team must help them manage their immediate emotional reactions so they can take necessary and curative actions on their children's behalf.[185] The behaviors of the nurses and the rest of the care team are critical in helping the patients and families cope and adapt as they endure what may be the greatest challenge of their lives.

Immediately after patients and families are told of recurrence, they are thrust once again into a state of waiting and not knowing.[56] During these difficult times, nurses support the patient and family by listening and providing them with opportunities to express their feelings. They may be confused about some of the information they have received and may feel angry, helpless, and overwhelmed as they contemplate decisions about additional treatment and realize they must once again take on the immense challenge of making decisions about their children's care. Collaborating with the health care team and coordinating the day-to-day care of siblings and work responsibilities may also add to parental distress. At this early stage, parents are especially dependent on physicians, nurses, and other health care professionals to communicate clearly and to share information about the illness and treatment that will help them plan and carry out their lives over the next weeks and months.[56]

At the time of recurrence, patients and families may express dissatisfaction with the initial treatment choice and may blame themselves for the treatment's ineffectiveness, calling themselves failures.[186] Parents often vacillate between hope for another remission and anticipatory grief while they struggle to determine whether they need to fight for cure or prepare for loss. These conflicting feelings are a part of coming to terms with the relapse, a process that involves limiting immediate emotional responses so they can take appropriate action.[185]

As treatment begins, patients and parents may become extremely vigilant about many of the details of therapy, such as the time a medication should be administered and the results of laboratory tests. Nurses and other providers must understand that such selective and watchful awareness is normal at this time and that it reflects the patients' and parents' need to gain control of the situation. During this time, parents often benefit from having predictable care routines and periods of time, however brief, in which they are free of any immediate worries. Such periods, parents say, help them to rest and recover from the burden of recurrence.[185] It is critical that the patient's needs for support not be overlooked or minimized in the mistaken belief that children are too young to understand the implications of recurrence. Research has shown that nurses who realize that school-aged children may be aware of the uncertainty associated with relapse support patients more appropriately than do nurses who believe the patients are unaware of the status of their disease.[187]

Studies show that parents who have experienced the relapse of their child's illness note the value of being kept apprised of treatment options and of how their children are responding to treatment.[185] Nurses address this need by speaking with family members during each encounter, reviewing what the families have been told, verifying information, answering questions, and helping them put new information into perspective.[56] Parents who have gone through the experience of the relapse of their child's illness also note the comfort they felt whenever providers demonstrated personal knowledge of or fondness for their children. Such actions, they said, told them that regardless of the treatment's outcome, their children would never be forgotten.[185]

NURSING CARE OF CHILDREN AT THE END OF LIFE

When efforts to treat the disease are unsuccessful, end-of-life care becomes critical.[188] As noted in a landmark report by the Institute of Medicine, the goal for children and families who face life-threatening diseases should be access to a health care system that provides "competent, consistent, and compassionate care that families can count on for support and solace as they experience a loved one's grave illness or death."[189] Unfortunately, many children who die of terminal illness in the United States do not receive aggressive supportive care at the end of life.[190] Historically, palliative care research in pediatrics has been difficult to conduct, owing to the sensitive nature of the topic and the reluctance of providers and parents to accept the inevitability of the situation at hand. Although this has been improving over time, additional efforts are needed to deliver more effective end-of-life care, educate professionals, and design supportive public services.[189] In spite of these challenges, many nurses and other health care providers have found that participating in end-of-life and bereavement care is a richly rewarding experience.

Nurses play critical roles in delivering end-of-life care because they provide most of the physical care while the patients are in the hospital and are key sources of support for patients and families while they are at home. The nurse has a unique appreciation of the patient's clinical condition, emotional needs, and family dynamics. Their observations and assessments are crucial to the efforts to keep the child comfortable and enhance quality of life. The family, or legal guardians, rely on the nurse as a give or vital information and support because they often have many questions and concerns.

End-of-Life and Palliative Care

Many of the challenges encountered when caring for patients and families at the end of life begin before the child enters the terminal phase of illness. Managing pain and other symptoms and coping with anxiety are issues for many patients with cancer. Palliative care, a specialized area of practice that focuses on preventing or relieving suffering and ensuring the best possible quality of life, is particularly important for patients at the end of life.[190,191]

Palliative care is both a philosophy of care and an organized, highly structured system of delivering care. Palliative care seeks to enhance patients' quality of life in the face of terminal illness. Palliative, or supportive, care should begin as soon as the child receives a diagnosis of a life-threatening condition and should continue throughout treatment until death, should it occur. The term *hospice care* refers to palliative care services (including therapeutic interventions and medical equipment) that are generally provided by a multidisciplinary group of physicians, nurses, chaplains, health aides, and bereavement counselors.[192]

An increasing number of hospitals and other health care organizations have organized teams of trained palliative care providers that consult with the patient's primary care team and provide guidance regarding the physical, emotional, developmental and spiritual needs of the child and family. These teams include physicians, nurses, social workers, and chaplains.

One of the most difficult decisions a family can face is deciding when to shift the focus from finding a cure to managing the end of a child's life. Historically, the conclusion that no curative options remain was arrived at solely by the treating physician. More recently, however, the parents or guardians have been routinely included in making end-of-life decisions, and the dying child may be included as well. In some cases, the family's decision about whether to shift the focus to end-of-life care may be complicated by an offer to participate in a clinical trial or to receive some form of innovative care. For the patient and the family these opportunities are usually unexpected, and deciding whether to participate in a trial or try a new treatment can be very difficult. Deciding what is right can also be difficult for health care providers who are also clinical investigators. They may experience discordance between their desire to advance science and improve the care of other children and their desire to protect the dying child by doing all that is in the child's best interest. This discordance may be lessened by the certainty that the dying child (when possible) and the family have been given all of the available information about the study and that they are making a well-informed decision.[193]

When discussing further treatment options or end-of-life care with a patient and family, clinicians must take the time to communicate clearly. How they approach the discussion should reflect appreciation of the child's developmental stage, how the child understands death, and awareness of the family's culture. The nurses who are caring for the child should be involved in the discussions because the family often calls on the nurse to interpret the information they have been given. A recent integrative review on parent perspectives on the care of their child at end of life found that recurring themes in the literature included poor communication with the health care team, inadequate emotional support, the parent's need to maintain their relationship with the child during end-of-life, availability of health care services impacting the child and family's quality of life, and the difficult decision to terminate life support.[194]

The nurse's primary goal when caring for a child or adolescent dying of cancer is to maximize the patient's quality of life. Nursing interventions are based on the patient's needs and on the patient's and family's style, values, spirituality, culture, and ways of relating to and interacting with others. To identify and support the unique needs of each patient and family, nurses assess the family's structure, dynamics, coping mechanisms, cognitive and emotional functioning, previous history with loss, family support system, and spiritual and religious beliefs on a continual basis, and the plan of care is developed and revised accordingly.

Nursing Care in the Inpatient Setting

Nurses focus on preventing illness, alleviating suffering, and protecting, promoting, and restoring health. However, when the restoration of health is no longer possible, the care shifts to ensuring the highest possible quality of remaining life and a comfortable, dignified death. When a child is facing the death in the hospital, maintaining comfort and helping the patient and family cope are the major priorities. Often nurses provide all of the child's clinical and physical care so that parents and other family members are free to meet the emotional needs of the child.

During the hospital stay, a focus of care is to normalize the patient's daily activities. Depending on the child's age and developmental stage, this may mean encouraging parents to go for a walk with the child, read the child a story, or give the child a bath. Working with the other members of the care team, the nurse may introduce play therapy that helps the child to express and cope with fears and anxieties.[195] Throughout the child's hospitalization, the nurse should try to maintain consistent caregivers and routines, because this may decrease anxiety for the child and family.

Outpatient, Home, and Hospice Care

Many children with progressive cancer die at home. Helping a child or adolescent to die peacefully at home presents a multitude of challenges to the care team, but it is critically important because the support of providers can enhance the family's ability to cope with the child's death. In the United States, much of the palliative and hospice care outside the hospital is currently provided by specially trained community nursing agencies; however, palliative care is a rapidly growing specialty in medicine and nursing, and many new services are being developed by hospitals, skilled nursing facilities, and other groups and providers.

Nurses in hospital and clinic settings play central roles in helping to arrange for home-based services and to ensure good communication between home care providers and clinicians in the hospital and clinic. When a patient is hospitalized, an inpatient case manager (often a nurse or social worker) is usually charged with identifying and arranging the community resources. Once the patient is discharged, the outpatient pediatric oncology nurse usually coordinates communication between the clinic and the care providers in the community. If home care services are not available or are not covered by health insurance, outpatient nurses may play a more central role in coordinating care among the provider, patient, and family.[196]

Hospice is a philosophy of care that is rooted in the centuries-old idea of offering a place of shelter and rest, or "hospitality," to weary and sick travelers on long journeys. The term was first used in 1967 by Dame Cicely Saunders of St. Christopher's Hospice in London to describe specialized care for dying patients.[197] The hospice philosophy recognizes death as the final stage of life and seeks to enable patients to continue alert, pain-free lives and to manage other symptoms so that they may spend their last days with dignity and surrounded by their loved ones. Hospice affirms life and neither hastens nor postpones death. It treats the person rather than the disease and emphasizes the quality, rather than the length of, the person's life. Hospice care should be initiated when the patient can no longer benefit from curative treatment, and life expectancy is, at most, no longer than 6 months. If the patient's condition improves or the disease goes into remission, hospice discharge can be arranged and the patient can return to active treatment if they desire.

Hospice services provide family-centered care 24 hours a day, 7 days a week. Although it can be given in a hospital, nursing home, or private hospice facility, most hospice care in the United States is given in the patient's home, with a family member serving as the primary caregiver, and the hospice staff offering ongoing consultation, guidance, and support. Care is focused on relieving pain and other symptoms and providing social, emotional, and spiritual support. Many hospices also provide respite and bereavement care. Choosing a hospice service can be a difficult decision for patients and families, and nurses and other providers often help by assisting them in gathering information and helping them to choose a hospice service that will meet their needs. Because many providers are unfamiliar with the programs and hospice options that are available, The Joint Commission has created a list of questions that patients, families, and providers can use to guide their selection of a home care or hospice program.[198]

Unfortunately, pediatric hospice services are not as widely available as services for adults. Often the nursing agency that provides home care during treatment also provides palliative care at the end of life. Because round-the-clock, home-based pediatric nursing care is available only sporadically, most of the burden of care is placed on the parents. In some cases, enlisting the help of a surrogate caregiver to maintain daily routines and provide respite for the parents may be helpful.

Nurses are integral members of the hospice care team focusing on meeting the physical, emotional, and spiritual needs of patients and families. Hospice nurses work independently, providing care in settings that are removed from many of the resources available in hospitals. Although the limits, functions, and titles of nurses involved in hospice care may vary from state to state, all hospice nurses are guided by the same holistic hospice philosophy and by a position statement from the American Nurses Association regarding the care of the dying patient that reinforces the obligation to promote comfort and ensure aggressive efforts to relieve pain and suffering.

The primary role of hospice nurses is to coordinate the care of a patient at the end of life while maintaining a focus on comfort not cure. In the course of providing care within the patient's home, hospice nurses observe, assess, and record symptoms and work with the child's physician or nurse practitioner to develop and help the family implement a plan that ensures optimal end-of-life care. Family members caring for the patient rely on hospice nurses for guidance in identifying and treating symptoms and for instruction regarding who to call for assistance.

One of the major concerns at end of life is the fear of intractable pain that can lead to serious problems, such as sleeplessness, loss of morale, fatigue, irritability, restlessness, and withdrawal.[198] Because nurses often have the most frequent and continuous contact with patients, they play central roles in assessing and managing the patient's pain and other distressing symptoms at this critical time.

Bereavement Care

Grief and bereavement are highly individualized and are influenced by the family's culture, community, faith, and support system. For many grieving families, abruptly ending contact with health care providers can feel like abandonment.[188] There are organizations that developed bereavement care programs through which professionals, volunteers, other families, and community agencies work together to meet the needs of a family, should this be needed.

Nurses, physicians, and other care providers often experience grief when a patient dies. Some may identify with the family and feel sad about the death, whereas others may experience awkwardness and not know how to respond. Needs of health care providers working with dying children vary according to their personal and professional experiences. Contrary to popular belief, nurses and other clinicians do not become accustomed to working with dying children; however, caregivers who have developed coping skills over time are probably better equipped to deal with the care of a dying child.[186,196]

Nurses, and other providers, who cope effectively tend to recognize their own feelings, take advantage of support groups provided by the health care institution, have an established support network outside the hospital, understand their own limitations as health care providers, and feel their contributions to the patient's care have been positive. Those who detach themselves as the child's death approaches, or who become overly involved and focus on the dying child and the child's family to the exclusion of their own personal needs, tend to have a more difficult time coping with the child's death.[196]

Nursing Education about End-of-Life Care

The care of dying patients is enhanced when it is provided by nurses who are experienced in and knowledgeable about end-of-life care.[199] Among the barriers to providing optimal palliative care are lack of formal courses in palliative care, high reliance on trial-and-error learning, lack of strong role models, and limited access to services focusing on pain management and palliative care, although this has changed dramatically in the past 10 years.[200] Recognizing these barriers, many groups in the nursing community have made educating nurses regarding palliative and end-of-life care a priority.

In 1998, the American Association of Critical Care Nurses published a document specifying competencies that nursing students should acquire related to end-of-life care. Since then, APHON has developed a curriculum and standards related to end-of-life care for training nursing staff and the End-of-Life Nursing Education Consortium, which is composed of nationally recognized palliative care experts, has created a curriculum to train nurse educators in palliative and end-of-life care and prepare them for teaching nursing students and practicing nurses. To date, over 15,000 health care providers have been trained in the United States and 73 other countries.[199] Palliative care content has been included in licensing examinations for nurses and has been added to nursing textbooks.[200]

In addition to training staff nurses in end-of-life care, there is also a need for nurses who have advanced knowledge and skills in palliative care, and graduate nursing programs include palliative care tracks for nurse practitioner students.[200] Nurse practitioners and nurses at the bedside who have such expertise can play vital roles in caring for patients by leading organizations and programs that care for patients at the end-of-life.

ETHICAL NURSING PRACTICE

Complex patient care problems present themselves daily in pediatric oncology practices. Because of the interdisciplinary nature of pediatric oncology, many problems that involve ethical implications are foreseen, and anticipatory ethics is practiced.[201] Nurses dealing with ethical issues are guided by the Code of Ethics outlined by the American Nurses Association[202] (Box 69-7) and by the ethical standards for Pediatric Oncology Nursing Practice defined by APHON (Box 69-8).[15] These documents highlight fundamental principles of ethical practice, including respect for persons, beneficence, and justice that are considered basic to nursing and that underpin how nurses think when confronted by problems involving ethical tensions.[201,203]

Box 69-7 **The American Nurses Association Code of Ethics for Nurses**

1. The nurse, in all professional relationships, practices with compassion and respect for the inherent dignity, worth, and uniqueness of every individual, unrestricted by considerations of social or economic status, personal attributes, or the nature of health problems.
2. The nurse's primary commitment is to the patient, whether an individual, family group, or community.
3. The nurse promotes, advocates for, and strives to protect the health, safety, and rights of the patient.
4. The nurse is responsible and accountable for individual nursing practice and determines the appropriate delegation of tasks consistent with the nurse's obligation to provide optimum patient care.
5. The nurse owes the same duties to self as to others, including the responsibility to preserve integrity and safety, to maintain competence, and to continue personal and professional growth.
6. The nurse participates in establishing, maintaining, and improving health care environments and conditions of employment conducive to the provision of quality health care and consistent with the values of the profession through individual and collective action.
7. The nurse participates in the advancement of the profession through contributions to practice, education, administration, and knowledge development.
8. The nurse collaborates with other health professionals and the public in promoting community, national, and international efforts to meet health needs.
9. The profession of nursing, as represented by associations and their members, is responsible for articulating nursing values, for maintaining the integrity of the profession and its practice, and for shaping social policy.

From American Nurses Association: Code of ethics for nurses with interpretive statements, 2010. Accessed January 28, 2013 at http://www.nursingworld.org/MainMenuCategories/EthicsStandards/CodeofEthicsforNurses/Code-of-Ethics.pdf.

Box 69-8 **Association of Pediatric Hematology and Oncology Nurses: Ethical Standards of Pediatric Oncology Nursing Practice**

Standard: The pediatric oncology nurse respects the rights of all children and families and makes decisions and designs interventions that are in agreement with ethical principles.

Rationale: Advances in technology and genetics, along with scarce resources in health care, have created an environment in which ethical issues frequently arise. The pediatric oncology nurse should advocate for the rights of children with cancer as well as identify and help resolve ethical conflicts.

Measurement Criteria:

The pediatric oncology nurse

- Understands and applies the basic ethical principles of autonomy (right to self-determination), beneficence (do what is in the best interest of the patient), nonmaleficence (do minimal harm), justice, and veracity (truth telling).
- Examines own beliefs relating to autonomy, rights of a minor, quality of life, death, suffering, truth telling, equality, and access to care.
- Identifies available resources, including the *Code of Ethics for Nurses with Interpretive Statements* (ANA, 2001) when formulating ethical decisions.
- Maintains confidentiality.
- Provides quality care to all children, regardless of race, culture, educational background, religious beliefs, socioeconomic status, or the ability to pay.
- Delivers care in a manner that preserves and protects patient autonomy, dignity, and rights.
- Acts as a patient advocate and assists children and families in developing skills so they can advocate for themselves.
- Identifies ethical conflicts and seeks to resolve them through multidisciplinary team discussions, including the child and family as appropriate.
- Addresses advance directives with young adults 18 years of age and older.
- Seeks to include minors in decision making as appropriate.
- Ensures that all children and families receive truthful information regarding diagnosis and treatment.
- Participates in the informed consent process by witnessing the signing of consent documents, obtaining ongoing education about research trials, answering the child and family's questions regarding their participation in research, and ensuring the child and family's continued desire to participate in the research trial.
- Reports illegal, incompetent, impaired, or unethical practices.
- Maintains therapeutic professional nurse-patient relationship with appropriate boundaries.

From Association of Pediatric Hematology/Oncology Nurses: Scope and standards of pediatric oncology nursing practice. *Silver Spring, Md., 2007, Nurses Books.*

Several factors must be present for high-quality, ethical nursing care to occur. Perhaps the most important factor is that the nurses themselves must be moral individuals, possessing integrity, courage, honesty, and a sense of justice.[195] Further, they must be willing to use these virtues to protect patients' rights to self-determination and to ensure that an individual's wishes, goals, and viewpoints are considered when managing care.[195,204,205] Nurses who frequently confront ethical issues benefit from forums that facilitate moral and ethical discussions, communication, and inquiry and that promote the exploration of options for patients. Guided sessions that focus on sorting through choices and their implications help nurses to gain a deeper understanding of nursing ethics and encourage them to embrace their role as patient advocate. The education provided by such forums not only helps nurses to develop skills needed to work through options when difficult situations arise but also helps them to cultivate the field of nursing ethics.[201]

The ways in which nurses approach ethical practice are somewhat different from the approaches used by other disciplines.[206] The differences may have their origins in the very core of each profession. Nursing and medicine, for example, often play complementary and virtually inseparable roles but have functionally different foci: nursing, a health-oriented profession, is focused predominantly on the care of patients and families while preserving and restoring health; medicine traditionally has been oriented toward the treatment, prevention, and cure of illness.[207] Because of these differences, the relationship that develops between patients and nurses can be very different from that which develops between patients and physicians.[208] Although both nurses and physicians serve as patients' advocates, the nurses' perspectives are informed by their proximity to the bedside, a proximity that allows nurses to develop unique relationships with patients and to witness directly the converging influences that surround care versus cure.[204,207,209]

During the course of pediatric oncology care, the varied and often complementary perspectives of each discipline have legitimate places in supporting the needs of patients and families. Nurses and physicians share responsibility for ensuring high-quality patient care and for achieving the best possible outcomes.[203] Further, because the uncertain nature of cancer renders the children and their families vulnerable, the practices of both disciplines must possess the moral virtues of honesty, courage, and justice and must reflect commitment to ethical principles.[195,209]

Ethical dilemmas related to care are often unavoidable. Nurses and physicians alike have the responsibility to manage with care the trust shown them by their patients. And when the right or good thing to do is not clear, they must have the moral courage to analyze critically and, if necessary, to challenge practices and health policies so as to ensure the best possible outcomes.[203,195,210,211]

FUTURE TRENDS IN ONCOLOGY NURSING

Change is intrinsic to the nursing profession and to pediatric oncology nursing, which remains a dynamic subspecialty that is subject to constant advances in technology and science and the introduction of new treatment regimens.[3,4,7] Faced with the potential for a nursing shortage, direct and deliberate strategies to integrate these changes into nursing education, practice, and research are required to ensure that pediatric oncology nurses are positioned to continue providing high-quality care.[7] In the coming years, as new treatments are introduced and more aspects of care shift to the outpatient setting and the home, it is expected that the role of the pediatric oncology nurse will continue to expand and assume greater importance. Remaining current with new developments in the field will make it possible for nurses to influence pediatric nursing practice effectively and to develop innovative strategies for managing the care of patients and families.[4,7,22]

No single discipline can accomplish all that is necessary for a patient; therefore collaboration is critical.[13] Research has shown that interdisciplinary collaboration is associated with improved outcomes, suggesting that intensifying nurse-physician partnerships based on mutual trust, respect, teamwork, and open communication is a priority.[21,22,35,212] Even though both nurses and physicians recognize the importance of collaboration, developing such partnerships may be a challenge.[213]

The primary focus of pediatric oncology nurses is healing rather than curing, but nurses will continue to play strategic roles in supporting the pursuit of a cure whenever possible.[22,32,214] As the consistent provider at the bedside, nurses have a distinct advantage to support translational research efforts. Leveraging this position by combining theory, research, science, and practice allows nurses to bring knowledge from the bench to the bedside and from the bedside to the bench.[215,216] The wide-ranging interests of pediatric oncology nurses and concerns include problems with care delivery systems, worries about meeting the needs of individual patients and families, and worries about national and global issues that impede clinicians' efforts to provide the best possible care to children with cancer.[216]

Moral and Sociopolitical Influences

The United States spends more on health care than most developed countries yet does not compare favorably with quality indicators of other high-performing health care systems.[217] The signing of the Patient Protection and Affordable Care Act in 2010 has been a catalyst of insurance reform and the introduction of cost reduction strategies within health care institutions. Viewed by some with skepticism and concern, the intent is to improve desired outcomes such as access, quality, equity, efficiency, and overall public health.[217] Although the aftereffects of health care reform on the health and well-being of children with cancer are not yet fully understood, in a setting of scarce resources understanding the multifaceted aspects of social and moral justification for health policy and the relationship to the various dimensions of well-being for children with cancer may be an initial signal of moral urgency for nurses who have a professional obligation to promote good health.[208]

With cancer identified as 1 of the 10 most expensive medical conditions, having generated an annual cost of $124.6 billion in 2010 alone, the National Cancer Institute predicts that costs associated with cancer care will reach $160 billion within the next 10 years as new targeted therapies are introduced.[218] Although much of the published data surrounding the rising costs of cancer care is associated with adult cancer treatment, the incidence of pediatric cancer has increased by 29% during the past 20 years. Long-term childhood survival rate of 79% for all childhood cancers and empirical reports also suggest there is increased complexity associated with childhood cancer treatment when compared with adult cancer.[17,18] The emergence of improved cure rates in pediatric cancer is now highlighting not only the cost of pediatric cancer care but also the long-term costs associated with survivorship. Nurses will need to fully use their unique knowledge, skill, and insight into the human experience developed by the interrelationships that occur with patient and families to facilitate an informed dialogue to influence health policy and reform at a local and national level through involvement in professional organizations such as the American Nurses Association and APHON.

Cancer Treatment and the Roles of Nurses

Current trends toward shorter hospital stays and more outpatient therapy demand that pediatric oncology providers change their focus and pay more attention to evaluating the burden of care that is placed on families and to supporting patients and families through the treatment process.[3,8,159,219] Helping patients and families to strengthen their personal support networks, learn about the disease, understand treatment options, and become knowledgeable about managing symptoms and side effects must continue to be a major focus for nursing and the entire health care team.[50,109,220]

Helping patients adjust to the diagnosis of cancer has become an increasingly important part of pediatric oncology nurses' roles. Research has shown that hope has a powerful influence on a patient's psychological and physiologic defenses.[221] These findings have significant implications for nurses, who work with patients and families to capitalize on their determination, courage, and optimism, helping them to develop a vision of hope, regardless of the child's age or the extent of disease.[221]

In the coming years, nursing's paradigm of professional practice will continue to shift toward a more holistic approach that requires knowledge of integrative therapies.[21,222] Therapies and interventions that strengthen the ability of the body and mind to influence healing are increasingly popular among pediatric oncology patients and families. As noted earlier, studies have found that as much as 85% of children and adolescents have used some form of integrative therapy.[101,102] These figures highlight the idea that developing an understanding of the risks and benefits of combining integrative therapies with traditional medicine is an important consideration for pediatric oncology nurses, now and in the future.[104,223] A committee formed by the Children's Oncology Group has highlighted the role of pediatric oncology nurses in CAM research and has noted that nurses are critical to the success of research in this area.[99]

Patient Safety

In 1979, NASA's Aerospace Human Factors Research Division linked inadequate communication, leadership, coordination, and decision-making skills, rather than pilot error, to most aviation accidents.[224] Since then, many health care organizations have translated this work into training courses designed to maximize teamwork among health care workers.[224] Clinicians participating in these courses have found that learning to communicate effectively and developing an understanding of one another's roles, responsibilities, and skills yields valuable insights and can positively influence the quality of patient care.[36] Such training programs will become increasingly important as organizations search for ways to minimize medical errors and improve the safety of the care environment.

Systems issues and other factors make many of the actions of nurses and physicians especially vulnerable to error. Nurses and physicians routinely make high-consequence decisions based on their knowledge and experience and an understanding of the relationship between patient-specific variables and environmental factors, such as work-flow patterns and the activities and norms of the patient care unit.[225] At times, these decisions are made in the context of factors such as conflicting goals, obstacles, unpredictability, poorly designed technology, constant change, hazards, and missing data that contribute to medical errors or near misses.[225] Maintaining vigilance in analyzing systems of care, identifying factors that contribute to errors or omissions, and introducing sustainable practice changes to promote safe patient care will continue to be a critical part of patient safety efforts.[226-228]

In many organizations, the growing focus on patient safety has impacted the culture of the work environment, shifting it from one that condones silence and blame to one that encourages open disclosure and promoting a team approach to problem solving.[229] Nurses in direct care roles confront patient safety directly and are important members of these problem-solving teams. They will continue to play critical roles in preventing medical errors and promoting safety in the health care environment.[229]

Self-Care

Nurses and physicians alike must find ways to preserve their interest in and passion for the work of caring for others. Although working to save, improve, or prolong the lives of others is rewarding, health care professionals often find that such work entails significant stress. This is particularly true in subspecialty practices like pediatric oncology, where patients are incredibly challenged by their diseases and often face uncertain futures. In addition to the emotional stress that stems from the focus on healing and helping, pediatric oncology providers often encounter workload and system constraints that contribute to chronic secondary stress and may lead to burnout or compassion fatigue.[230]

Understanding the concept of self-care and self-management is a pragmatic consideration for pediatric oncology nurses. Knowing how to renew oneself is critical to maximizing professional effectiveness and satisfaction.[21,22]

Nursing Research

The research training, methods, and rigor of nurse scientists are consistent with those of any other scientific disciplines. Through the lens of professional nurses, research questions spanning the continuum of the cancer trajectory guide oncology nursing care. Based on a holistic model (Fig. 69-1), the needs of the patient and family are addressed using evidence-based strategies that help them cope with the physical and emotional sequelae of the cancer experience.

Figure 69-1 A continuum of oncology nursing research. *Research emphasis area of the National Institute of Nursing Research; †Priority area of the Oncology Nursing Society. *(From Bauer-Wu S, Epshtein A: Dana-Farber Cancer Institute, 2007.)*

patient-oriented research have made noteworthy strides in the past decade as nurses have sought to change clinical practice on the basis of existing evidence. This trend toward evidence-based practice is widespread in the nursing community. The past decade has also witnessed a trend toward clinically based nurse-scientists who can bridge the knowledge gap between academia and clinical practice. More doctorally prepared nurses contributing to science will help to support a shift in the research paradigm to one that is multidisciplinary in nature, with nurse-scientists contributing to large multisite studies. This shift means more nurse scientists will have to be trained as members of larger multidisciplinary research teams.

A review of studies conducted by nurse researchers and of surveys among oncology nurses suggests that future nursing research will continue to focus on understanding the full scope of the patient experience and on identifying nursing interventions that ease the hardship of disease for patients and families alike.[231-233] Some of the high-priority areas for future nursing research include the following:

- Understanding issues related to long-term survivorship
- Enhancing patients' quality of life, with a focus on the management of pain and symptoms
- Evaluating and improving care at the end of life
- Evaluating and promoting safe and effective nursing practice in all care settings, including the home
- Understanding families' perspectives to find ways to support patients and families
- Developing new ways to incorporate nursing research into practice and to promote and support interdisciplinary research

These priorities are consistent with the strategic plan and overall mission of the National Institute of Nursing Research (NINR) to advance the science of health by enhancing health promotion and disease prevention; improving quality of life by managing symptoms of acute and chronic illness; improving palliative and end-of-life care; enhancing innovation in science and practice; and developing the next generation of nurse-scientists.[234] They also reflect pediatric oncology nurses' appreciation for the ways in which cancer impacts patients and families and the toll it takes on their physical, psychological, and social well-being. The priorities also exhibit nursing's continued commitment to preventing illness; to alleviating suffering; to protecting, promoting, and restoring health; and to ensuring a comfortable and dignified death and the highest possible quality of life when the restoration of health is no longer possible.

The advances in pediatric oncology that have occurred over the past half century are responsible for a remarkable increase in the number of patients who are cured; however, many patients still face uncertain futures and require ongoing care and support by health care professionals. Although the benefits to patients and families of an interdisciplinary approach to care cannot be underestimated, it is widely acknowledged that pediatric oncology nurses play a vital role in the care of patients and families. The knowledge, skills, and caring practices demonstrated by expert pediatric oncology nurses not only enhance the abilities of patients and families to cope with diagnoses of cancer but also help to reduce the overall burden of the disease.

KEY REFERENCES

8. Forte K: Pediatric oncology nursing: providing care through decades of change. *J Pediatr Oncol Nurs* 18:154–163, 2001.

Pediatric oncology nursing practice has evolved over the years as new technology and trends in health care have necessitated change. Reflections of three pediatric oncology nursing leaders and a review of the literature demonstrate advances in treatment and supportive care.

15. Association of Pediatric Oncology Nurses, American Nurses Association: *Scope and standards of pediatric oncology nursing practice*, Silver Spring, MD, 2007, Nurses Books.

Standards of practice and standards of professional performance are outlined for the pediatric oncology nurse and the pediatric oncology advanced practice registered nurse (APRN). The standards are critical for guiding pediatric oncology nurses in delivering high-quality nursing care.

27. Heiney S, Wiley F: Historical beginnings of a professional nursing organization dedicated to the care of children and adolescents with cancer and their families: the Association of Pediatric Oncology Nursing from 1974–1993. *J Pediatr Oncol Nurs* 13:196–203, 1996.

In 1974, the Association of Pediatric Oncology Nurses (APON) was established based on the philosophy that pediatric oncology nursing is a specialty that requires specific knowledge and expertise in the care of children who have cancer. This distinction was formalized with the development of specialty certification in pediatric oncology nursing in 1993.

34. Curley M: *Synergy: The unique relationship between nurses and patients*, Indianapolis, IN, 2007, Sigma Theta Tau International.

This model describes what nurses do based on levels of expertise and building of optimal nurse-patient relationships. Nurses from all roles and subspecialties can apply this framework to their practice.

38. Ponte PR, Conlin G, Conway J, et al: Making patient-centered care come alive. *J Nurs Admin* 33:82–90, 2003.

The concept of patient-centered care is espoused in many health care organizations, yet implementing this framework has been challenging for many. This article describes how patient-centered care has been implemented within a major cancer center in the United States.

46. Hooke M: Psychosocial issues. In Kline N, Brace-O'Neill J, Hooke M, et al, editors: *Essentials of pediatric oncology nursing: a core curriculum*, ed 2, Chicago, 2004, Association of Pediatric Oncology Nurses, pp 196–227.

Psychosocial issues including care of families, culturally sensitive care, spirituality, school reentry, and professional nurse-patient relationships are discussed with emphasis on pediatric and adolescent and young adult cancer patients.

49. Holm K, Patterson J, Gurney J: Parental involvement and family-centered care in the diagnostic treatment phases of childhood cancer: results from a qualitative study. *J Pediatr Oncol Nurs* 20:301–313, 2003.

This qualitative study describes how parents of children with cancer participate in their child's medical care. Parents emphasized they advocated for their child during treatment, educated themselves about the disease and therapy, and worked with the medical team. Recommendations for practice included implementing a family-centered care approach and inclusion of parents regarding treatment decisions.

57. Mack J, Grier H: The day one talk. *J Clin Oncol* 22:563–566, 2004.

This article describes the salient features of the discussion with parents at the time of their child's cancer diagnosis. Three main features of the talk are emphasized: the cancer diagnosis, treatment and causation.

59. Vaartio-Rajalin H, Leino-Kilpi H: Nurses as patient advocates in oncology care: activities based on literature. *Clin J Oncol Nurs* 15:526–532, 2011.

This literature review found that oncology nurses assessed their patients both physically and psychologically and developed plans of care, starting with the diagnosis. The literature emphasizes the importance of patient education regarding cancer treatment and the informed consent process.

75. Cescon D, Etchells E: Barcoded medication administration: a last line of defense. *JAMA* 299:2200–2202, 2008.

The two processes from which preventable accidental disconnection and exposure most commonly arise are medication prescribing and administration. Barcoded medication administration (BCMA) systems are a last line of defense against medication errors and warrant greater advocacy and implementation.

78. Conley S: Safe handling of chemotherapy and biotherapy agents. In Kline N, Hesselgrave J, O'Hanlon-Curry J, editors: *The pediatric chemotherapy and biotherapy curriculum*, ed 3, Chicago, 2011, Association of Pediatric Oncology Nurses, pp 65–69.

Occupational exposure risks and exposure prevention guidelines including personal protective equipment, preparation and administration guidelines, disposal of chemotherapy, body fluid guidelines, exposure guidelines, spill management, and safe handling in the home are discussed.

108. Fochtman D: The concept of suffering in children and adolescents with cancer. *J Pediatr Oncol Nurs* 23:92–102, 2006.

Individual suffering needs to be defined and measured by self-report (as opposed to parent or staff report) to gain an accurate, complete holistic picture of the nature and scope of the child's and adolescent's suffering. Knowledge of how children and adolescents experience suffering would enable practitioners to design interventions to prevent or ameliorate this suffering.

111. Hockenberry M: Symptom management research in children with cancer. *J Pediatr Oncol Nurs* 21:132–136, 2004.

A review of the literature revealed that children with cancer continue to experience distressing physical symptoms caused by the disease and treatment. The purpose of this article is to provide a concise overview of the most common symptoms experienced by children with cancer including pain, nausea and vomiting, nutritional concerns, mucositis, and fatigue.

121. Kline N: Prevention and treatment of infection. In Baggott C, Kelly K, Fochtman D, et al, editors: *Nursing care of children and adolescents with cancer*, ed 4, Philadelphia, 2011, WB Saunders.

As immunity wanes during cancer treatment children and adolescents become susceptible to infections. A comprehensive review of bacterial, viral, and fungal infections is presented along with prevention and treatment guidelines.

153. Margolis P, Muething S, Brilli J, et al: Quality transformation efforts: decreasing PICU catheter-association bloodstream infections: NACHRI's. *Pediatrics* 125:206, 2010.

The purpose of this multiinstitutional study was to develop and evaluate effective catheter-care practices to reduce pediatric catheter-associated bloodstream infections (CA-BSI). Results suggested that the main reasons for additional reductions in pediatric CA-BSI rates are issues that surround daily maintenance care for central lines, and additional research is needed to define the optimal maintenance bundle to reduce CA-BSIs in children.

154. Secola R, Lewis M, Pike N, et al: "Targeting to zero" in pediatric oncology: a review of central venous catheter–related bloodstream infections. *J Pediatr Oncol Nurs* 29:14–27, 2012.

The purpose of this review of the literature is to summarize existing adult and pediatric data on central venous catheter–related bloodstream infections and explore nursing models of central venous catheter care that may improve pediatric oncology patient outcomes.

193. Hinds P, Kelly P: Helping parents make and survive end of life decisions for their seriously ill child. *Nurs Clin North Am* 3:465–474, 2010.

American parents of chronically ill children prefer to be involved in decision making about their ill child's end-of-life care. Parents report that having access to understandable information about their child's health status influences their ability to participate in end-of-life decisions.

196. Fochtman D: Palliative care. In Baggott C, Fochtman D, Foley G, et al, editors: *Nursing care of children and adolescents with cancer and blood disorders*, Chicago, 2011, Association of Pediatric Oncology Nurses, pp 468–501.

The focus of pediatric palliative care is to enhance the quality of life for the terminally ill child by preventing and alleviating suffering using the skills and knowledge of a specialized care team. Pediatric palliative care focuses on pain and symptom management, information sharing and advance care planning, practical, psychosocial and spiritual support, and coordination of care.

199. American Association of Colleges of Nursing: The End-of-Life Nursing Education Consortium (ELNEC), 2013. Accessed March 1, 2013 at <http://www.aacn.nche.edu/elnec/about/fact-sheet>.

The ELNEC program is a national initiative to provide nurses with training in palliative care. More than 17,500 nurses and other health care providers from all 50 states and 77 additional countries have received ELNEC training.

202. American Nurses Association: Code of Ethics for Nurses with Interpretive Statements, 2010. Accessed January 28, 2013 at <http://www.nursingworld.org/MainMenuCategories/EthicsStandards/CodeofEthicsforNurses/Code-of-Ethics.pdf>.

The code of ethics for nurses outlines the nonnegotiable ethical obligations and duties of individuals entering nursing practice and is an expression of nursing's understanding of its commitment to society.

224. Oriol M: Crew research management. *J Nurs Admin* 36:402–406, 2006.

Lessons from the aviation industry, which long ago acknowledged that most errors were the result of poor communication and coordination rather than individual mistakes, are applied to the health care setting. Examples are given of how health care organizations have successfully adopted aviation's curriculum called "Crew Resource Management," which promotes and reinforces the conscious, learned team behaviors of cooperation, coordination, and sharing.

234. National Institute of Nursing Research: Bringing Science to Life: NINR Strategic Plan, 2011. Accessed February 24, 2013 at <https://www.ninr.nih.gov/sites/www.ninr.nih.gov/files/ninr-strategic-plan-2011.pdf>.

Released in 2011, the NINR strategic plan identifies 25 years of accomplishments in nursing science, specifically those that have the greatest potential to improve the health of the nation. The plan is based on the idea that individuals would benefit from being actively involved in maintaining their own health from prevention of disease and self-management of illness.

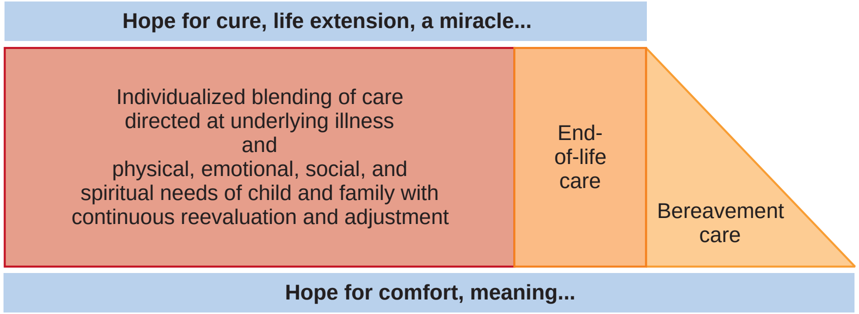
ONGOING CHALLENGES

More than 2000 children die each year in the United States of cancer-related causes, and many more are living with advanced cancer.[1] In children with cancer, it is not always possible to determine whether the disease will be responsive to cancer-directed therapy, nor is it possible to determine which type of path the dying process will take. Some children may die suddenly and unexpectedly, such as a child undergoing bone marrow transplant who experiences a treatment-related complication. Others may experience a steady and fairly predictable decline, such as the child with a progressive brainstem glioma after radiation therapy. Most children with progressive cancer will experience varying periods of chronic illness punctuated by crises, one of which may prove fatal. An example of this type of path may involve a child with relapsed metastatic neuroblastoma who may be palliated long term before experiencing a life-ending event.

Although intensive, interdisciplinary supportive care, that is, palliative care, is essential for all children with cancer, it is especially critical for children living with



Hope for cure, life extension, a miracle...
Individualized blending of care directed at underlying illness and physical, emotional, social, and spiritual needs of child and family with continuous reevaluation and adjustment
End-of-life care
Bereavement care
Hope for comfort, meaning...

Figure 70-1 Pediatric palliative care includes individualized integration of palliative care principles to ensure combined hopes of varying degrees related to life extension and comfort, both of which can last throughout the child's life. End-of-life care is an important component of palliative care when the focus of care is almost entirely on comfort, although hope for a miracle can persist. Bereavement care needs can be intense and long lasting, gradually lessening over time.

more advanced stages of cancer. Involvement of palliative care services has been shown to improve symptom detection and identification of communication needs among children with advanced cancer,[2] but as of 2008, only 58% of Children's Oncology Group institutions had dedicated palliative care services available, suggesting that there is still room for improvement.[3] Nonetheless in recent years there has been greater awareness and integration of palliative care and, with this, care more consistent with its principles.[4]

Palliative care, as defined by the World Health Organization,[5] is an approach to care that improves the quality of life of patients with life-threatening illness and their families, through the prevention and relief of suffering by means of early identification, assessment, and treatment of pain and other problems, whether physical, psychosocial, or spiritual. The organization's definition of palliative care appropriate for children and their families is as follows:

- Palliative care for children is the active total care of the child's body, mind, and spirit and also involves giving support to the family.
- Palliative care begins when illness is diagnosed and continues regardless of whether a child receives disease-directed treatment.
- Health care providers must evaluate and alleviate a child's physical, psychological, and social distress.
- Effective palliative care requires a broad multidisciplinary approach that includes the family and makes use of available community resources; it can be successfully implemented even if resources are limited.
- Palliative care may be provided in tertiary care facilities, community health centers, and the home.

Hospice and Palliative Medicine (HPM) became a formal physician subspecialty in 2006, and, currently, to become board eligible, a physician needs to complete a 1-year accredited fellowship program. However not all children with cancer require care by a HPM subspecialist or pediatric palliative care (PPC) team. Basic palliative care knowledge, skills, and behaviors should be known to all clinicians who care for children with life-threatening illnesses and conditions. The role of the HPM subspecialist and team is to provide clinical consultation for more complex situations, to provide education and training, and to improve palliative care outcomes for all children and families through quality improvement and research.

In fact both data[6,7] and clinical experience favor a blended approach to care that includes disease-directed treatments together with palliative or comfort care. This approach is most often favored by parents, who commonly hope for life prolongation while also desiring maximal comfort and minimal pain and suffering for their child (Fig. 70-1). Pediatric palliative care should not be a choice between life-prolonging treatments (e.g., chemotherapy for cancer) and palliative care. Rather pediatric palliative care should be integrated into an overall care plan that is individualized and adaptable over changing circumstances.

INTEGRATING PALLIATIVE CARE FROM THE TIME OF DIAGNOSIS

Although palliative care and end-of-life care are often considered to be a single entity, it is important to note that palliative care can be initiated at any time, not just in the end-of-life period. Rather than being restricted to the last phase of life, palliation includes attention to symptoms from the time of diagnosis. Palliative care also allows for discussion of goals and preferences for care long before death occurs.

In addition rather than precluding intensive life-prolonging care, palliative care can be complementary to therapy with curative intent. With the inclusion of palliative care early in the disease course, children can benefit from attention to symptoms and quality of life concurrent with efforts to control disease. Parents often have many goals of care beyond cure or life prolongation. Parents of children who died of cancer, for example, recall holding simultaneous goals of extending life and minimizing suffering during their child's treatment course.[7,8] Concurrent disease-directed care and attention to the physical, psychosocial, and spiritual needs of the child and family may be the optimal approach to meeting these seemingly conflicting goals.

Among some pediatric cancer patients, such as children with pontine gliomas, the pattern of progression is relatively predictable, making planning for the end of life a logical part of care from diagnosis. Patients with other cancers, however, may have long periods of disease control and relative clinical stability. Although ultimately the child may be expected to die of the disease, which relapse or acute decompensation will result in death can be very difficult to predict. Early relapses may be responsive to intensive treatment, and the timing of death may be difficult to predict.

For a child with relapsed neuroblastoma, for instance, many years may elapse between the first recurrence and death. At any moment in time, the use of intensive chemotherapy may seem reasonable and may offer significant hope of life prolongation and remediation of symptoms. However repeated intensive therapies including chemotherapy-related toxicity may not coincide with the family's wishes for the end of the child's life and may be associated with unnecessary suffering for the child. Even when families choose life-extending measures, they should have the opportunity to do so in the context of an understanding of the expected path of illness.

Advantages of Early Integration of Palliative Care

Before the patient is clearly in the last phase of life, physicians may find it difficult to initiate conversations about a poor prognosis.[9] But the majority of parents of children with cancer say they want prognostic information, even when the news is upsetting.[10] Patients and families who are poorly prepared for death tend to choose more intensive disease-directed care at the end of life.[8,11] Without realistic information, they may not have the opportunity to make choices for care that are consistent with their values.

Just as physicians sometimes prefer not to discuss prognosis, pediatricians sometimes consider palliative care to be equivalent to hospice care. As a result they may integrate palliative care concepts such as advanced care planning and anticipatory guidance only once curative options have been exhausted.[12] Yet families may find earlier integration of palliative care to be helpful. A study of bereaved family members of adult cancer patients, for example, found that half believed that palliative care was provided too late in the disease course, whereas less than 5% believed palliative care referrals occurred too early.[13] Physician communication was found to be an important contributing factor; families who believed that the physician had communicated effectively about the patient's prognosis and end-of-life care were less likely to believe that palliative care was introduced too late.

Early initiation of palliative care facilitates attention to symptoms and quality of life. Involvement of palliative care services improves symptom detection and identification of communication needs among children with advanced cancer.[2] Similarly adults with advanced cancer tend to experience improvement in symptoms, including pain, anorexia, nausea, vomiting, sleeplessness, and constipation, after referral to palliative care services. In addition patients who receive palliative care frequently experience improvements in overall quality of life and well-being.[14]

It is also possible that early discussions about palliative care can help parents to cope with the death. Mothers who experience the sudden death of a child tend to have more intense grief than mothers whose children die after a chronic condition.[15] These findings raise the possibility that emotional and psychological adjustment before a child's death can help parents to cope with the loss of the child over time.

Perhaps most importantly parents value preparation for the end-of-life period. In a study of bereaved parents of children with cancer, physician communication about what to expect in the end-of-life care period was a component of high-quality care.[16] Parents who felt prepared for the circumstances surrounding the child's death were also more likely to consider care to be of high quality overall. Communication with parents in advance of the child's death may allow them to process and be prepared for the death before it happens and to make choices about end-of-life care that are right for them and their child.

Box 70-1 gives some general guidance for discussion about end-of-life preferences.[17,18] Even if the patient's outcome is uncertain, death can be discussed as a possibility so that the patient has opportunities to express goals for care.

Enhancing Integration of Palliative Care When Cure is No Longer Possible

Although integration of palliative care from the time of diagnosis is often ideal, sometimes a clinical event such as relapse or a severe complication makes it necessary to discuss a poor prognosis for the first time. A transition from care intended to cure the child can be experienced as a terrible loss for families. However as with discussions about care at the time of diagnosis, honest communication about the child's prognosis can help the family make reasonable decisions about care, based on their values.[19]

Delays in parental understanding of a poor prognosis can affect the care they choose for their children. In a study of parents of children who died of cancer, parents recalled understanding that the child was likely to die about 3 and one half months after the physician realized this. Earlier parental realization of the low likelihood of cure was associated with increased hospice use and decreased cancer-directed therapy in the end-of-life care period.[8] Although parents sometimes have difficulty accepting a poor prognosis, the difficulty physicians have in communicating a poor prognosis also contributes to parents' overly optimistic expectations about cure.[20]

MAKING THE TRANSITION TO PALLIATIVE CARE

Discussing a Change in Prognosis

A statement that physicians can use when introducing this discussion with parents is, "Although I had hoped that your child's disease would be cured and your child could live a long life, I am now worried that this is no longer possible."[18] Acknowledging the sadness of the situation, responding to the parent's emotions, and allowing for silence can also be helpful. Parents may ask about treatment options, but such discussion should not obscure the fact that the child's disease is unlikely to be cured.

Box 70-1 **Communicating with Children and Families About Integrating Palliative Care**

BEGINNING THE CONVERSATION

"What is your understanding of what is ahead for your child?"

"Would it be helpful to talk about how his or her disease may affect him or her in the months and years ahead?"

"As you think about what is ahead for your child, what would you like to talk about with me? What information can I give you that would be helpful to you?"

INTRODUCING THE POSSIBILITY OF DEATH

"I am hoping that we will be able to control the disease, but I am worried that this time we may not be successful."

"Although we do not know for certain what will happen for your child, I do not expect that your child will live a long and healthy life; most children with this disease eventually die because of the disease."

"I have been noticing that your child seems to be sick more and more often. I have been hoping that we would be able to make him or her better, but I am worried that his or her illness has become more difficult to control and that soon we will not be able to help him or her to get over these illnesses. If that is the case, he or she could die of his or her disease."

ELICITING GOALS OF CARE

"As you think about your child's illness, what are your hopes?"

"As you think about your child's illness, what are your worries?"

"As you think about your child's illness, what is most important to you right now?"

"You mentioned that what is most important to you is that your child be cured of his or her disease. I am hoping for that, too. But I would also like to know more about your hopes and goals for your child's care if the time comes when a cure isn't possible."

INTRODUCING PALLIATION

"Although I hope that we can control your child's disease as long as possible, at the same time I am hoping that he or she feels as good as possible each day."

"Although it is unlikely that this treatment will cure your child's disease, it may help him or her to feel better and possibly to live longer."

TALKING ABOUT WHAT TO EXPECT

"Would it be helpful to talk about what to expect as your child's illness gets worse?"

"Although we cannot predict exactly what will happen to your child, most children with this disease eventually have [difficulty breathing]. If that happens to your child, our goal will be to help him or her feel as comfortable as possible. We can use medications to help control his or her discomfort."

TALKING TO CHILDREN

"What are you looking forward to most of all?"

"Is there anything that is worrying you or making you feel afraid?"

"Is there anything about how you are feeling that is making you feel worried or afraid?"

From Mack JW, Wolfe J: Early integration of pediatric palliative care: for some children, palliative care starts at diagnosis. Curr Opin Pediatr *18:10–14, 2006.*

The physician might respond to such requests by saying, for instance, "It is possible that treatment might help your child to feel better and possibly live longer; the hope would be for the treatment to control the cancer for as long as possible." Although these conversations are difficult for families and for medical providers, such honesty can help parents to make the best possible decisions for their child. In addition although honest provision of information is important, physicians may be able to clarify the goals of care without needing to have parents necessarily openly acknowledge that cure is not likely; this approach may be preferable to some parents.

Discussing Goals of Care

An important aspect of providing care for children with cancer is an understanding of the goals of care. Often these goals are identified by the parents, but adolescents and even younger children are often able to define priorities for their care as well.[21] Understanding goals of care allows the medical team to make recommendations for care that fit with patient and family values. In addition goals of care, and conversations about these goals, provide another window into parents' perceptions of what is ahead.

A discussion about goals of care can be started by asking parents what is most important to them as they think about what is ahead for the child.[18] Specific questions about hopes for the future and worries about what is ahead can also be useful. Often parents will verbalize general goals, such as maintaining a good quality of life for as long as possible, minimizing suffering, prolonging life, or curing the child's cancer. Parents often hold more than one goal and may have separate goals for cancer-directed and symptom-directed therapy; for example, goals of cancer-directed therapy may be to cure or to prolong life, whereas goals of symptom-directed therapy may be to lessen suffering and maximize quality of life.[8,7] Although such goals may appear to be conflicting, holding more than one goal of care is normal, and physicians can make plans for care with both sets of goals in mind.

Acceptance of the parents' goals is an important aspect of acknowledging the parents' values, even when the goals are not in concert with the physicians' goals. At times, however, parents will continue to articulate a goal of cure, when the medical team believes that such an outcome is not possible. Understanding what the parent would want if the child cannot be cured can help the medical team to make plans for care. Back and colleagues[22] have recommended that the physician ask what the family would want if cure is not possible, a strategy described as hoping for the best but preparing for the worst. This strategy allows the medical team to have a conversation about what the family would want in such a situation.

Even when parents hold goals of cure, physicians need to have clear discussions about the goals of treatment, especially cancer-directed treatment. Depending on the circumstances, the oncologist may want to express goals of controlling the disease for as long as possible, for example. When the purpose of treatment is to help cancer research, with little hope of direct benefit to the child, that goal also should be stated.

In addition to the specific nature of goals of care, parents also consider a number of other values while they make these difficult decisions. For example parents sometimes think about what it means to be a good parent to their child as one compass for decision making.[23] Parents may believe, for instance, that a good parent would focus on preserving the child's life, would make unselfish decisions in the child's best interest, or show the child that he or she is loved. In addition to helping parents clarify their own wishes, having conversations about the meaning of the good parent role can help clinicians to reinforce that role as the child's illness progresses.

Similarly parents may use phrases to sum up the things that are most important to them: "I want the best for my child;" "I have to fight;" "I want my child to have quality of life."[24] By listening for and probing these phrases, clinicians partner with parents in clarifying their goals and making decisions. Ultimately these conversations about parents' values allow clinicians and the parents themselves to recognize their values, enact them in the child's care, and work together during these very difficult times.

Eliciting Children's Goals

Children and adolescents may express goals in general terms, like their parents, or they may have very specific wishes, such as staying at home, spending time with siblings, or minimizing invasive procedures.[21,25,26,27] Knowing about these goals, which can be elicited by asking children for their hopes and worries, and what is most important to them when they think about what is ahead, can allow the medical team to work toward meeting any specific hopes or needs.

Creating a Plan for Care Based on Goals

Once goals of care have been elicited, then a plan of care can be made. It is important to acknowledge that this plan is flexible and may change frequently. Importantly each family is unique, and even with similar goals there may be very different plans of care. As previously mentioned, pediatric palliative care should be integrated while a family is seeking a life-prolonging or potentially curative therapy. Therefore a plan of care may include preventative therapies, looking for life-prolonging or curative therapies, rehabilitation, and intensive quality of life and symptom management.[28] Having parents consider these questions may help them with decision making.

- How will this treatment affect my child's quality of life?
- What is likely to happen without this treatment?
- How will the treatment change my child's prognosis?
- What will it be like for my child (and family) to go through this treatment?
- Are there other options we should consider that might have the same outcome but with a different approach?

Particularly as cure becomes less likely, helping parents to think deeply about what brings a child joy or which experiences provide quality of life may help their decision making. Ideally the child will be included in these decisions and plan of care. In one study, children aged 8 to 17 years wanted to be told if they were dying and adolescents in particular wanted to participate in palliative care decisions.[29]

Appointing a Health Care Proxy

For patients older than 18 years, the decision of whom to appoint as a health care proxy may provide an opportunity for discussion of care preferences. This document, often completed on admission to the hospital, allows the patient to designate someone to make medical decisions if the patient is unable to do so. The proxy ideally makes decisions based on knowledge of what the patient would want in various situations and not on what the proxy would want or believe to be appropriate. Most hospitals have standard forms that are completed by the patient and an admissions staff person. This could be an opportunity to explore the true wishes of the young adult patient and lead to rich discussion and meaningful decision making.

Resuscitation Status and Other Aspects of Advance Care Planning

Advance care planning may include (1) designation of a decision maker or, for those older than 18 years old, choosing a health care proxy; (2) discussion of the illness and prognosis; (3) establishment of goals of care; (4) discussion of preferences for resuscitation, artificial nutrition and hydration, and palliative sedation; (5) primary location of care and death; and (6) discussion about organ or tissue donation, including autopsy, and preferences for funeral arrangements.[30] Advanced care planning is a process that requires time and often occurs through multiple conversations and at different phases of the child's illness.

Of note many clinicians believe that these conversations happen later than they should.[31] Clinicians cite multiple barriers to discussions about advance care planning, especially unrealistic parent expectations about the child's illness, differences between clinicians' and parents' understanding of prognosis, and a lack of parent readiness to have these conversations. Clinician perceptions about parent understanding or readiness, however, should not preclude having these conversations. Physicians also report that they often do not know what to say.[31]

Fortunately several resources are available to assist in these discussions. *Five Wishes* (for those >18 years) (available at www.agingwithdignity.org) is a legal document in 37 states. This document presents information and questions in a way that enhances communication about these difficult subjects, and it addresses what kinds of nonmedical interventions would be wanted, such as music, prayer, presence of family, and so on. *My Wishes* (for those <18 years) (also available at www.agingwithdignity.org) is not a legal document, but through simple questions and the opportunity to write and draw it affords the child or adolescent the opportunity to communicate his or her wishes. In addition *Voicing My Choices* has been recently developed for adolescents and young adults aged 16 to 28, using materials from *Five Wishes* and modified after interviews with adolescent and young adult patients with cancer or who are infected with human immunodeficiency virus.[26] This work involves four priority areas, which can serve as a model for younger patients as well: the ability to express and document preferences for (1) the medical treatment they want and the treatment they do not want; (2) how they would like to be cared for; (3) information they want family and friends to know; and (4) how they want to be remembered.

Other techniques may be helpful, such as asking an adolescent to name his or her wishes, realistic or not. The provider may also ask a question such as, “What is your understanding of your illness now?” Another technique is to suggest that the adolescent write, with a trusted person, such as a child life specialist, psychosocial clinician, or parent, what questions he or she would like to ask of the health care team. Ideally advance care planning among adolescents is family centered, with the family and adolescent both taking part in shaping wishes for care, in an effort to develop a plan for care that all can support.[32] Doing so can allow families to understand their adolescent’s wishes and ultimately carry out these wishes.

Making Recommendations

Even when curative therapies are no longer sought, families report wanting recommendations regarding available interventions. Most do not want the burden of making decisions completely on their own. Providers may believe that, especially when there are treatments with uncertain or marginal benefit, plans for care should be the parents’ choice. However parents can often be best supported by providers who clearly discuss the positives and negatives of each treatment or therapy and then recommend a treatment in the context of the family’s goals and values. This can apply to a wide spectrum of situations such as participating in a phase I or II clinical treatment trial, putting in a chest tube for pleural effusions, using intravenous antibiotics to treat an infection, or instituting a do not resuscitate (DNR) order. Clinicians who make recommendations can alleviate this burden from the parents and help to minimize the parents’ sense of regret and responsibility for choices that ultimately allow death to occur.

COMMUNICATING PLANS FOR CARE

A plan of care must then be communicated to all involved in the child’s care. Consistency and honesty are among what bereaved parents tell us is most important.[33] Written documentation of team meetings, family meetings, and the care plan is essential. Documentation can also help to communicate plans of care with other providers, such as the home care team or those providing emergency services. Along with a home DNR or comfort care form, for instance, a letter that documents the child’s situation and plans for care can be carried by the parents to help ensure that any care providers they encounter know their goals for care. By partnering with the child and family, the health care team in the hospital or home has the opportunity to enhance quality of life while the child is living and affect the grieving and bereavement that will follow for the family.

Talking with Children about Advanced Illness

To tell or not to tell? This is the question that typically arises when parents and health care providers of children with life-threatening illnesses face the issue of discussing prognosis with children. Health care providers have reported a wide range (10% to 80%, with a median 45% prevalence) of open discussions among parents and children regarding the child’s impending death.[34] Of a sample of 429 parents in Sweden, 34% discussed death with their child, and none of those parents regretted having this discussion. When children were given the information that their illness was terminal, most (63%) received it from the parent and physician together.[35] In addition, several studies have shown that children as young as 6 to 10 years old are willing to participate in end-of-life decision making.[21,36] Parents’ and health care providers’ distress in navigating these communication processes (especially regarding death) may prevent children and families from accessing appropriate and timely pediatric palliative care.[37]

Parents may be reluctant to discuss death with their child because of the understandable worry that such a conversation may be very upsetting to the child. However children may have some understanding that death is likely but, because they sense the parents’ distress, may feel unable to discuss this topic with a parent. This choice often stems from concern for the parent’s well-being. Providing the child with an opportunity to talk, however, can be therapeutic for the child. We therefore often encourage parents to allow for such an opportunity. For parents to initiate discussion, they need to be supported for their efforts in broaching and carrying out these difficult conversations with their child.[38] When parents were asked how they best could be supported during end-of-life care of their child, they responded by saying that respect for the family’s role, comfort, spiritual care, access to care and resources, communication, support for parental decision making, and caring/humanism were central.[39]

By describing to parents a nonthreatening mode of communication when carrying out discussions with their child, centered on exploring what the child knows and what the child may be worrying about and hoping for in the time ahead, we can often reassure parents that this conversation will be sensitive and guided by the needs of the child.

The needs and wishes of the individual child should guide how communication takes place and its content. A child’s age and level of cognitive development as well as the changing comprehension of death by age can help shape the appropriate conversations regarding the prognosis, treatment choices, and end-of-life decisions; however, all this information cannot necessarily predict what a child understands about death.[40] Furthermore depending on the disease (e.g., brain tumor), the act of communication may be functionally difficult on the part of the child.[41] Thus careful assessment of a child’s physical abilities, maturity, level of comprehension, and coping abilities rests on the family and health care team. Himelstein[30] explains appropriate communication interventions (i.e., language, details, expression, participation) based on age (Table 70-1). Chesler and colleagues found that the age at which the child was diagnosed with cancer was strongly and significantly related to the amount of information the parents provided about the illness: the older the child, the more information was given.[42]

TABLE 70-1 Development of Death Concepts and Spirituality in Children

Age Range	Characteristics	Predominant Concepts of Death	Spiritual Development	Interventions
0-2 yr	Has sensory and motor relationship with environment. Has limited language skills. Achieves object permanence. May sense that something is wrong.	None	Faith reflects trust and hope in others. Need for sense of self-worth and love.	Provide maximal physical comfort, familiar persons, transitional objects (favorite toys), and consistency. Use simple physical communication.
>2-6 yr	Uses magical and animistic thinking. Is egocentric. Has thinking that is irreversible. Engages in symbolic play. Is developing language skills.	Believes death is temporary and reversible, like sleep. Does not personalize death. Believes death can be caused by thoughts.	Faith is magical and imaginative. Participation in ritual becomes important. The need for courage is important.	Minimize separation from parents. Correct perceptions of illness as punishment. Evaluate for sense of guilt and assuage if present. Use precise language (dying, dead).
>6-12 yr	Has concrete thoughts.	Develops adult concepts of death. Understands that death can be personal. Is interested in physiology and details of death.	Faith concerns right and wrong. Eternal interpretations may be accepted as the truth. Ritual is connected with personal identity.	Evaluate child's fears of abandonment. Be truthful. Provide concrete details if requested. Support child's efforts to achieve control and mastery. Maintain access to peers. Allow child to participate in decision making.
>12-18 yr	Has generality of thinking. Sees reality as objective. Is capable of self-reflection. Sees body image and self-esteem as paramount.	Explores nonphysical explanations of death.	Internal interpretations start to be accepted as the truth. Relationship with God or higher power evolves. Meaning, purpose, hope, and the value of life are sought.	Reinforce child's self-esteem. Allow child privacy. Promote child's independence. Promote access to peers. Be truthful. Allow child to participate in decision making.

From Himmelstein BP, Hilden JM, Boldt AM, et al: Pediatric palliative care. N Engl J Med *350:1752–1762, 2004.*

However, in another study that retrospectively collected information regarding psychosocial variables on 45 pediatric oncology patients who died, it was found that children between the ages of 3 to 6 years had more information about their own death from their parents than older children between the ages of 7 to 11 years. The investigators concluded that perhaps children in the younger age group had a "magical concept" of death, thus making it easier for caregivers to discuss end of life with these younger children.[43] Hurwitz and colleagues provide questions and statements children raise about dying at various ages, thoughts that guide the behavior, their underlying developmental understanding of death, and strategies and responses that can help children in these situations (Table 70-2).

Assessing the child's level of autonomy, perception of threat and safety, and individual coping style can help the clinician determine how to communicate with the child regarding palliative care. Independence and individuation will vary. For example, some adolescents, especially those who have close relationships with their parents, may not make a lot of the day-to-day decisions on their own and depend on their parents' authority and life experience for critical decision making. Other adolescents may be accustomed to "heading" the household and making many of the daily decisions for a family.[44]

Understanding the child's family history with regard to illness and experience with death are important components to consider when broaching sensitive issues within palliative care. A child who has previously witnessed a relative die or suffer from a serious illness and observed his or her family's grief may have unique needs related to this experience. Children who are accustomed to making decisions along with their siblings may request to have siblings present during important decision-making events.

Understanding whether the child has a current and/or premorbid history of anxiety and/or depression is also critical in how information is delivered during advanced care planning discussions.[45]

TABLE 70-2 Statements About Dying at Various Stages of Development

Examples of Questions and Statements About Dying	Things That Guide Behavior	Developmental Understanding of Dying	Strategies and Responses to Questions and Statements About Dying
1-3 Years			
“Mommy, after I die, how long will it be before I’m alive again?” “Daddy, will you still tickle me while I’m dead?”	Understanding of accidental events, of future and past time, and of the difference between living and not living is limited.	Death is often viewed as continuous with life. Life and death are often considered alternate states, like being awake and being asleep, or coming and going.	Maximize physical comfort, familiar persons, and favorite toys. Be consistent. Use simple physical contact and communication to satisfy the child’s need for sense of self-worth and love. “I will always love you.” “You are my wonderful child, and I will always find a way to tickle you.”
3-5 Years			
“I have been a bad boy, so I have to die.” “I hope the food is good in heaven.”	Concepts are crude and irreversible. The child may not distinguish between reality and fantasy. Perceptions dominate judgment.	The child sees death as temporary and reversible and not necessarily universal (only old people die). Because of their egocentricity, the child often believes that he or she has somehow caused the death or views it as a punishment. Death is like an external force that can get you and may be personified (e.g., the bogeyman).	Correct the child’s perception of illness as punishment. Maximize the child’s time with his or her parents. A child of this age may be concerned about how the family will function without him or her. Help parents accept and appreciate the openness of these discussions. Reassure the child and help parents lessen guilt that the child may feel about leaving by using honest and precise language. “When you die, we will always miss you, but we will know that you are with us and that you are in a safe, wonderful place” (perhaps with another loved one who has died).
5-10 Years			
“How will I die? Will it hurt? Is dying scary?”	The child begins to demonstrate organized, logical thought. Thinking becomes less egocentric. The child begins to problem-solve concretely, reason logically, and organize thoughts coherently. However he or she has limited abstract reasoning.	The child begins to understand death as real and permanent. Death means that your heart stops, your blood does not circulate, and you do not breathe. It may be viewed as a violent event. The child may not accept that death could happen to himself or herself or to anyone he or she knows but starts to realize that people he or she knows will die.	Be honest and provide specific details if they are requested. Help and support the child’s need for control. Permit and encourage the child’s participation in decision making: “We will work together to help you feel comfortable. It is very important that you let us know how you are feeling and what you need. We will always be with you, so you do not need to feel afraid.”
10-13 Years			
“I’m afraid if I die my mom will just break down. I’m worried that when I die, I’ll miss my family or forget them or something.”	Thinking becomes more abstract, incorporating the principles of formal logic. The ability to generate abstract propositions, multiple hypotheses, and their possible outcomes becomes apparent.	The child begins to understand death as real, final, and universal. It could happen to him or her or family members. The biologic aspects of illness and death and details of the funeral may begin to interest the child. The child may see death as a punishment for poor behavior. The child may worry about who will care for him or her if a parent or caregiver dies. He or she needs reassurance that he or she will continue to be cared for and loved.	Help reinforce the adolescent’s self-esteem, sense of worth, and self-respect. Allow and respect the adolescent’s need for privacy, but maintain his or her access to friends and peers. Tolerate the teenager’s need to express strong emotions and feelings. Support the need for independence, and permit and encourage participation in decision making. Although I will miss you, you will always be with me and I will rely on your presence in me to give me strength.”

TABLE 70-2 **Statements About Dying at Various Stages of Development** (Continued)

Examples of Questions and Statements About Dying	Things That Guide Behavior	Developmental Understanding of Dying	Strategies and Responses to Questions and Statements About Dying
14-18 Years			
"This is so unfair!" "I cannot believe how awful this cancer has made me look." "I just need to be alone!" "I can't believe I'm dying. … What did I do wrong?"	Thinking becomes more abstract. Adolescence is marked by risk-taking behavior that seems to deny the teenager's own mortality. At this stage, the teenager needs someone to use as a sounding board for his or her emotions.	A more mature and adult understanding of death develops. Death may be viewed as an enemy that can be fought against. Thus dying may be viewed by the teenager as a failure, as giving up.	"I can't imagine how you must be feeling. You need to know that despite it all, you are doing an incredible job of handling all of this. I'd like to hear more about what you are hoping for and what you are worrying about."

From Hurwitz CA, Duncan J, Wolfe J: Caring for the child with cancer at the close of life: "there are people who make it, and I'm hoping I'm one of them." JAMA *292:2141–2149, 2004.*

Within the framework of the American culture is the diversity of the various ethnic and religious cultural subgroups that utilize a range of guiding principles with regard to illness and truth-telling. It is critical to assess the family's identification with their particular culture and inquire what their beliefs are with regard to communication with children about issues pertaining to advanced care,[46] because this may vary from the protective approach (shielding young patients and siblings from full knowledge of the disease) to a more open approach.[42,47] Although every family's style of disclosing sensitive information may be different for a variety of reasons, health care providers should consider how parents may feel if they do not prepare their child for impending death, because this has been shown to have long-term implications for parental grief.[48]

Techniques for Communication

In many instances communicating with children regarding palliative care issues is best received when healthcare professionals are aware of the child's level of desired information and concurrently reinforce the primary role of parents.[49] Children between the ages of 8 and 17 years who were interviewed about disclosure regarding their diagnosis and prognosis reported a range of views about the form of disclosure they preferred: a few believed it was better to hear the news at the same time as their parents, some thought it was more appropriate for their parents to be told first, and others reported no strong feelings either way.[50] Patients reported the roles their parents performed in facilitating communication with their health care team: asking questions for them, being the source of information, and reframing the information from the health care team so they could understand it better. Some children reported feeling "protected" by the parent's executive role in screening the communication with doctors and "marginalized" by the nonparticipant status.[49] Parents of cancer survivors indicated that the shielding of information that took place (i.e., preference regarding whether to provide information to their child about prognosis and treatment options) depended on their child's age and emotionality.[51]

The range of views reported by pediatric patients exemplifies the necessity for tailoring one's approach of communication to the individual child. The most beneficial method for determining the most appropriate way to communicate with a particular child is by spending time with him or her. A provider who knows the child well may be best suited for this conversation whenever possible. Prior to the delivery of information, it is helpful to uncover what the child already knows. This can be done through direct conversation or through nonverbal communication (e.g., drawing and symbolic play). Storytelling, such as using the experience of another family with a child or a loved one facing death, may be another modality that can be used by parents and health care providers to broach sensitive topics related to death.[52] Ensuring privacy, confidentiality, and support can facilitate the trust that is needed for the child to disclose what it is that he or she already knows. The next step is finding out what the child wants to know. Then the clinician can give information in small amounts, responding to the child's reactions and feelings; and can remind the child that there will be additional opportunities to discuss the issues of concern.[40]

Listening

Listening to a child cannot be underrated nor underutilized. Because a child confronting a life-threatening illness is at his or her most vulnerable, listening to the child can be a very powerful tool in placing some of the control back in the hands of the child.[53] Allowing moments for silence in the discussion only reinforces this acknowledgement that the clinician is listening.[53] Providing a child with a tape recorder can be another method for empowering the child. This allows the child to record his or her questions for the upcoming appointment with the clinician, and also allows them to record the clinician's answers so they can be reviewed if necessary.[54] Asking about and listening to the child's priorities and providing choices, when possible, may allow the child to participate in "life-enhancing experiences even at the close of life."[55(p 746)] Listening to the voice of the parent(s) goes hand-in-hand with listening to the child to provide comprehensive family-centered care; it can provide helpful information about the child and make the health care provider a better listener for the child. Listening to the parent without the presence of the child can also be a valuable tool in certain instances when the child's presence may restrict communication.[56]

SPIRITUALITY

Spirituality can be regarded as a multidimensional (mind, body, spirit), unique expression that brings individuals hope, meaning, and purpose.[57] Spirituality is related to, but different from, religion, such that "spirituality is a dynamic state of being in which the individual seeks connectedness, whereas, religion represents the beliefs, values, practices, and rituals that are an observable aspect of a person's spirituality."[58(p 56)] Spirituality is often "inexpressible" whereas religion is marked by greater structure.[57] A child can have a "highly developed awareness of spiritual concepts without ever having been part of a formal religious group."[59(p 271)]

Spirituality in Children

Similar to the development of cognitive abilities, children display a developing awareness of spiritual needs, meaning, or purpose within their lives at various ages. During infancy, children find meaning in their daily life through unconditional love and trust. Toddlers desire self-assertion, worthiness, and success when performing new skills. Preschoolers and school-aged children tend to derive their satisfaction from learning concepts of right/wrong, impulse control, and the benefits of peer socialization. Adolescents find purpose in their developing independence, individuality, and a deeper relationship with a higher being.[59] For a child with a life-threatening illness, spiritual concerns often include a need for unconditional love, forgiveness, hope, safety and security, and development of a legacy. Children also often experience loneliness and loss of wholeness.[60] It can be helpful for children of all ages to be assured that they bring meaning to their families lives and that when they are no longer alive they will be remembered by their family.[57,61]

Children, in general, more than adults, tend to attribute an illness to "internal" (personal) factors, as opposed to "external" (environmental) factors. Children younger than the age of 7 years, who have yet to develop the ability to think abstractly, often see illness as a form of punishment for something they have done wrong (immanent justice belief).[58] Although some older children may attribute the illness to internal causes to maintain control, others are able to attribute the illness to external causes but also seek out the meaning and purpose of their illness—a task that is very often spiritual.[58]

The Spiritual Assessment

Because children tend to reflect the religious and spiritual values of their parents and family, a family-centered assessment of spirituality is often helpful. Providing spiritual care for parents can prepare them for the questions children ask, such as, "Why is God doing this?" or "What is heaven like"? Parents need assurance that there is no specific "right answer."[62]

One method for conducting a spiritual assessment is through the use of the B-E-L-I-E-F questions:[63]

*B*elief system (e.g., Does your family take part in religious events/rituals? Have you discussed the idea of afterlife with your child? Do you believe in a higher power that influences your life?)

*E*thics or values (e.g., What are the values you believe are most central to your family?)

*L*ifestyle (e.g., Are there rituals or dietary practices that you/your family follow?)

*I*nvolvement in a spiritual community (e.g., Are you involved with a spiritual community?)

*E*ducation (e.g., Do you/your family receive or have received religious education?)

*F*uture events (In the near future, are there any religious rites of passage set to occur for you or your family members? What role would you like the members of your faith community to play in the spiritual care of your child?).

However most spiritual counselors and chaplains discourage the use of a "checklist format" in assessing spirituality. Instead questions could be posed to the family and/or to the child in a conversation format depending on the situation.[59] Clinically effective pediatric spiritual assessments are conducted in narrative form and may use words, pictures, music, and play, thus inviting a child to explain his or her sources of strength and areas of fear. Discussions with children and their families regarding spirituality early on in the disease course can help bring meaning to what the family is enduring and can provide hope and comfort at end of life.[60] Assessing children's developmental understanding of faith using Fowler's stages of faith[64] can be helpful in knowing how to lead these spiritual conversations with children directly and how to guide parents in doing so:

Stage 1: Intuitive Projective Faith (2-7 years) is when children's thinking is filled with fantasy and notions of faith are based on stories usually told by parents and other caretakers.

Stage 2: Mythic-Literal Faith (7-12 years) incorporates children's knowledge of cause-and-effect relationships into separating fact from fantasy when constructing an understanding of faith and their religious expression.

Stage 3: Synthetic-Conventional Faith (12-21 years) is when adolescents are able to use abstract reasoning skills to develop their own spiritual identity by separating out what has been told to them and creating new connections between faith-based stories and their own beliefs.

Facing obstacles, challenges, and adversity in life often engenders spiritual thoughts and prompts adults and children alike to ask questions of a higher power, such as, "why me?" "why my child?" It is natural that spirituality is a significant issue for families of children with cancer.[57,65] Pastoral care providers at children's hospitals estimate that more than half of child patients can benefit from spiritual care for fear, anxiety, coping with pain, and familial difficulties.[66] Providers in this study identified three major barriers to providing spiritual care: "inadequate training of health care providers to detect patients' spiritual needs, inadequate staffing of the pastoral care office, and being called to visit with patients and families too late to provide all the spiritual care which could have been provided."[67(p e70)] When the focus of clinical care is on "the cure" for children, treatment discussions focus on medical facts and issues centered on resolving the "problem" with medications or therapies; spirituality, in palliative care, by contrast, is more about a journey of meaning, where there may be no clear solution.[57] Providing spiritual care to dying children and families requires the professional to face his or her own issues with spirituality, something not all individuals have done or are ready to do.[57] Children's spirituality tends to be overlooked and, as a result, children may be more likely to feel unheard, invalidated, and alone in the end-of-life period.[68] A focus on spiritual beliefs during the end-of-life period is not only critical to the dying patient but also can have implications for bereavement outcomes, such that people who profess stronger spiritual beliefs may experience a more rapid and complete sense of closure after the death of a loved one.[69]

SCHOOL

Going to school provides multiple benefits for the school-aged child with cancer. It is the child's peer group; it is the child's chance for discovery, mastery, and socialization.[70] Most children want to continue with their class unless they have not been well supported or they feel unable to participate. With the family and child's permission, creative solutions for participation can allow the child to remain in school often until just days before death. Preparation of school staff and classmates is important, as is a willingness on the family's part to allow for candid information about the child's illness and treatment course.

Ideally this information is shared soon after a child is diagnosed. Often hospital or clinic staff will travel to the child's school and provide information through a "back to school" program. The question frequently arises during these sessions as to whether the child/friend/peer will survive. Most school-aged children have known an adult with cancer, some who have survived and some who have not. Addressing this question in a hopeful way while acknowledging the uncertainty is essential. In all instances if the child dies, it is important for schools and communities to have a plan about ways to communicate this information and support classmates' questions, fears, and feelings.

One possible disturbing aspect of school attendance by the ill child may be the change in the child's physical condition. Reassuring classmates of the child's unchanging personhood may be necessary. Explaining absences, altered appearance, and altered ability to participate in regular class activities may also be helpful.

For the ill child to attend school, school staff and medical providers may need to be creative. Perhaps the child is allowed to attend for half days or just for lunch or on special activity days. Even limited time can be meaningful for the child and his or her peers. An individualized education plan (IEP) tailored to the needs of the child can also allow resources to be mobilized. An ill child should be able to receive home or hospital schooling, and some may be able to complete computer courses or stay in touch with the classroom via teleconferencing.

Advance Care Planning and the School System

As a child's disease progresses, the family and medical team may decide together that a DNR order should be in effect. This can present challenges as to how to honor this within a child's community. Many states are in the process of adopting medical orders for life-sustaining treatment[71] to provide consistent communication regarding advanced care decisions for loved ones no matter what the location of care. However most school districts do not have guidelines or policies to deal with this kind of situation, and those that do have policies typically prohibit school staff from honoring an order that would limit attempts on resuscitation.[72] Nonetheless ethical principles of beneficence, nonmaleficence, and autonomy have been offered as justification for honoring limits on attempts at resuscitation for the student.[72,73] At this point each child, family, and school will need to come to some clear agreement of whether abiding by medical orders for life-sustaining treatment would be observed if the child was at school during a life-ending event.[74-76]

Grief and Bereavement in the School

Finally anticipatory grief and bereavement needs of classmates and school staff must be considered. Resources are available (e.g., www.dougy.org); however affording the training and opportunities for staff to integrate this into their knowledge and experiential repertoire may be challenging. It may be helpful for the oncology clinicians who helped treat the child as well as palliative care staff to do an in-service or advise school personnel.[77] Because children with life-threatening illness are living longer, however, acceptance of their goals to enhance their quality of life must be honored whenever possible.

INTERDISCIPLINARY CARE

The interdisciplinary team is an essential aspect of palliative care for children.[28] How else could we possibly address the physical, social, emotional, and spiritual needs of the child with a life-threatening illness and the family as well?[78] Ideally the team is providing care from the time of diagnosis through death and bereavement.[18,28,79,80] Because care may occur in the hospital, home, or community, most often the child has a primary team (pediatrician or oncologist) whose members take the lead in day-to-day management. Most often the team consists of a physician, nurse practitioner or nurse, and social worker. Other core team members include a psychologist, chaplain, child life specialist, and case manager. The needs of the child and family require an entire team to provide the holistic care that is synonymous with palliative care.

Interdisciplinary care occurs with the child and family as partners. Priorities of the family are elicited, with their values, beliefs, and culture taken into account as recommendations are made that inform the necessary decision making. Family meetings, especially those used to address goals of care, include the parents, the child if appropriate, and interdisciplinary team members, so that information, emotional cues, and nonverbal language may be appreciated from different perspectives. This format also allows for a response that may address the issues holistically. In addition to those already mentioned, at times an interpreter, physical therapist, teacher, respiratory therapist, nutritionist, or pharmacist is present for the family meeting. Importantly, research has shown that when the physician is working with a psychosocial clinician there is closer agreement between the physician and parents in the understanding of the child's prognosis.[8]

Interdisciplinary care is essential so that not only the child's and parents' needs can be addressed but also those of the extended family, community groups, and the hospital, clinic, and home care staff. Particularly when doing a home visit, it is helpful to have several team members present so that physical and emotional needs of the patient, parents, and siblings may receive attention. Each team member carries the responsibility to inform, teach, and reach out to colleagues. Depending on one's clinical setting, there inevitably will be times that different team members are called on to take the lead.

Pediatric palliative care is particularly challenging. As providers, we have "an obligation to nurture relationships that can hold within their embrace both vulnerability and suffering: that which is experienced by our child patients and their families, and that which we experience within ourselves."[81] The depth and meaning of this care touches us at our core. We need the expertise, support, and companionship that interdisciplinary care provides.

COORDINATION OF CARE

The coordination of care for a child with a life-threatening illness who moves between hospital, home, clinic, and perhaps a rehabilitation facility is daunting. Despite the efforts of many providers, parents often report feeling overwhelmed with the responsibility of care and coordination of services, particularly in the home. There are many barriers to coordination of pediatric palliative care services, including lack of available staff to provide home-based services; limited training of staff in pediatric palliative and hospice care; few resources for services; limited agencies with comprehensive services; and insufficient systems to support communication and coordination between sites of care.[30] Ideally each hospital, clinic, community, or home care agency has designated personnel to perform coordination tasks for the child and family and has protocols specifying a standard of practice.[28]

Thankfully, in the United States a growing number of home care agencies have developed palliative care programs that serve as a bridge to hospice services for children not yet meeting hospice eligibility criteria (<6 months to live) or for those seeking intensive disease-directed therapies. Previously the reimbursement structure and use of medical technology (e.g., intravenous nutrition, assistive respiratory support), experimental therapies, and/or need for block hours of nursing care had precluded enrollment of children on the hospice benefit.

Importantly section 2302 of the recent Patient Protection and Affordable Care Act, termed the "Concurrent Care for Children Requirement" (CCCR) has eliminated the requirement that Medicaid patients younger than 21 years forgo curative or life-prolonging therapies to be eligible for hospice. Therefore Medicaid programs in every state are now required to provide concurrent curative/life-prolonging treatment and hospice services for hospice-eligible children. The development of systems to make such concurrent care a reality has been slow and, in the meantime, a number of state-based pediatric palliative care coalitions have formed to jumpstart access to home-based pediatric hospice/palliative care services, using strategies such as Medicaid waivers or state plan amendments to increase coverage for hospice services. For example Massachusetts implemented a statewide pediatric palliative care program in 2006.[82]

LOCATION OF DEATH

At the end of life, children and families often benefit from intensive support. It is generally assumed that children would prefer to be at home to die, although approximately half of children with progressive cancer die in the hospital,[83] as do the majority of infants and children who die in the United States.[84] In a study from the United Kingdom, research showed that of children dying in the hospital, 85.7% died in the intensive care unit, with the trend having increased over the years from 1997 to 2004.[85] Families and children need to feel safe and well cared for and given permission, if possible, to choose location of care, be that at home, in the hospital, or a hospice house. Asking children where they would most like to be even if they are very sick and what is most important to them is often very instructive.

Although seemingly contradictory, the philosophy of palliative care can be successfully integrated into a hospital setting, including the intensive care unit, when the focus of care also includes the prevention or amelioration of suffering and improving comfort and quality of life. All interventions that affect the child and family need to be assessed in relationship to these goals. This proactive approach focuses on what "we can do" not what we cannot do. We might ask what can we offer that will improve the symptoms and quality of this child's life (e.g., radiation therapy, a trip to the garden, a special visit from a pet) and provide the most meaning and control for their family instead of asking what interventions are not going to be offered. Staff needs education, support, and guidance because pediatric palliative care, like other types of intensive care, is an area of specialty.

Preparation for Home Care

Preparing parents for events that may occur at home is essential. Even if they may not want to talk about this, written materials can be offered. Anticipating likely symptoms, ways to manage the symptoms, what resources will best match needs, and who will be available on call 24/7 to the family is key to making the transition to home successful. The child's primary inpatient or clinic providers must work closely with the case managers and social workers who know the intricacies of insurance benefits, home care nurses, and durable medical equipment vendors and who can determine what each can and will provide. It is also important to reach out to the primary care provider, who may have important insights to the home environment and resources in the community.

Even the most experienced families still need maximum physical and emotional supports in the home to care for a child who is facing the end of life. The goal is to have enough support in place so that parents can simply be "parents" and so that family interactions and events may become meaningful experiences.

Hospice Services

For those families and children who know they want to be at home, hospice services can be invaluable. Many hospice agencies now have palliative care programs, which offer greater flexibility and broaden the scope of care. There are many barriers, however, to provision of hospice services to children even with the new legislation section 2302 of the Patient Protection and Affordable Care Act.[78] Many fewer children than adults die, and so maintaining a staff that is willing and able to provide care to children can be challenging. Families and practitioners often see hospice as "giving up," and it remains difficult to change this assumption. There is a prognostic requirement of life expectancy of less than 6 months, and this can be a significant emotional barrier for families and clinicians. Financially provision of hospice may also be a struggle, because hospice is mandated to provide all the personnel, medications, equipment, and supplies that the child needs and this is capped at a per diem rate.[86] The financial concerns may be mitigated with successful implementation of the Affordable Care Act, which should be reassessed over time.

The first free-standing pediatric palliative care center in the United States, the George Mark House, opened in 2004, and other pediatric hospice houses have followed. Some adult hospice houses are now willing and equipped to accept a child, with the hospice staff often appreciating the support of a previously involved pediatric palliative care team. In addition to hospice care there is a monumental unmet need for many families who are in desperate need of respite care for their child, who may have a prolonged palliative care path ahead of them.

Despite these barriers, palliative care, respite care, and hospice care for all children with life-threatening conditions is the recommendation of the Committee on Bioethics and Committee on Hospital Care.[80] Importantly when experienced in caring for children, hospice teams are ideally suited to provide comprehensive home-based services to the child, siblings, parents, and extended family. Hospice programs often have physicians, nurses, social workers, chaplains, and bereavement staff, art therapists, music therapists, pet therapists, and volunteers who can provide integrative therapies such as massage and Reiki.[87]

CANCER-DIRECTED THERAPY

Parents often wish to continue some form of cancer-directed therapy in the end-of-life care period and are more likely to favor using cancer treatment at the end of life than clinicians.[88] The choice of cancer-directed therapy should be considered in the context of goals of care. For example if a parent's primary goal is to minimize the child's suffering, then an option that causes few distressing side effects and that necessitates few interventions may be a reasonable choice, if parents wish to continue to provide cancer-directed therapy.

Some regimens with limited toxicity have established efficacy in relapsed or refractory tumors. For example, daily oral etoposide has been used in children with refractory solid tumors, with limited resulting toxicity and with the possibility of tumor response.[89-93] Oral temozolomide has had similar results in children with neuroblastoma.[94] In refractory acute lymphoblastic leukemia, maintenance-type regimens of 6-mercaptopurine, low dose methotrexate, vincristine, and prednisone may be effective without causing significant side effects. Antibody therapies, such as rituximab for children with B-cell malignancies, and molecular agents, such as imatinib in potentially responsive cancers, may also offer palliation with limited toxicity. Other examples of therapies with limited toxicity can be found in the literature.

Other parents may wish to continue more intensive regimens of chemotherapy. Recent work has found that, when prescribing chemotherapy for children with no realistic chance for cure, oncologists consider the potential toxicity of the chemotherapy, family preferences, and the potential that therapy will decrease cancer-related symptoms.[95] However, nearly half of oncologists studied had prescribed chemotherapy to meet parental wishes, and many oncologists' recent experiences with end-of-life chemotherapy did not meet their goals of prescribing. Thus physicians should ensure that such regimens offer reasonable hope of meeting the parents' and child's goals of care.

Parents may also wish to pursue experimental options such as those provided on phase I clinical trials. In general the likelihood of significant benefit from agents offered on phase I trials is limited, typically under 8%, even in children.[96] Misconceptions about the purpose of phase I trials are common; as with other clinical trials, many subjects believe that the purpose of such a trial is to benefit them personally rather than to benefit future patients.[97] When clinical trials are offered, clarity about the purpose of the trial is important so that parents and children can make informed decisions about whether such therapy will help to meet their goals. In addition such therapies do not preclude concurrent attention to symptoms and quality of life. In fact attention to life prolongation and symptoms simultaneously may best meet the needs of children with advanced cancer and their families.[98,99]

Other cancer-directed options to be considered include local irradiation or surgery. If a single lesion is causing significant pain or other symptoms, then localized radiation therapy may offer palliation with few systemic side effects. Radiation therapy directed at an isolated painful bony metastasis is one such example. Surgery can be similarly beneficial, but a frank team discussion with the surgeon about the possibility of recovery and the likelihood of recurrence can help in consideration of the likelihood that the child will benefit from the surgery. Debulking of a rapidly growing abdominal tumor, for example, may provide little benefit, in contrast to control of a single painful metastasis by radiation or surgery. A consistent recommendation between the oncologist and surgeon or radiation oncologist should be provided to the family.

Physicians sometimes feel an obligation to describe cancer-directed therapy as either “curative” or “palliative.” Such a distinction may be difficult, however, because at times cancer-directed therapy may offer some chance of cure, even if this chance is low, as well as some possibility of symptom palliation and life extension. In addition this distinction may be difficult for families, who may hold more than one goal for care. We recommend rather than using a label of curative or palliative, that cancer-directed therapy be discussed in terms of the goals for care. For example we may be able to tell parents that the goals of a particular therapy are to control the disease for as long as possible, with a very small possibility of cure, and with a higher likelihood of decreasing symptoms for a period of time. If cure is clearly not a goal of therapy, then that also should be stated.

Families who have been accustomed to using cancer-directed therapy at every recurrence may continue to pursue such options even when the medical team believes that the likelihood of benefit is extremely low. Unfortunately previous work suggests that parents may regret decisions made about end-of-life cancer treatment in retrospect,[100,101] especially if treatment involved suffering.[100] Thus clinicians should do everything possible to ensure thoughtful decision-making prospectively. In addition when such situations arise, the team should reach consistent recommendations about cancer-directed therapy and should not offer therapies with no chance of benefit and a high risk for harm. However patients and families will have different preferences for end-of-life care; and for some families, continuing to “battle cancer” until the time of death may hold personal meaning. The team should therefore follow the same standards for communication that we have described earlier: assess the family’s understanding of prognosis, allow for further communication about the prognosis if needed, elicit goals of care, come to a team consensus about plans for care that fit with goals, and make recommendations for care based on family and patient goals and the team’s consensus. Intensive interventions may be chosen by families who have overly optimistic perceptions of prognosis[8,11]; ongoing communication about the child’s prognosis may allow families to readjust goals and to choose interventions that offer realistic chances of benefit. The team should never be obligated to provide care that is considered to be inappropriately harmful and in such cases should work with hospital ethics teams to define appropriate responses to family requests. But beyond the reaches of harm, families who make thoughtful decisions about care for their children should be allowed to do so, even when plans for care do not match the ideals of staff members.

SYMPTOM-DIRECTED THERAPY

Managing symptoms for the child with a life-threatening condition is of utmost importance. Parents and children are partners in care and the experts regarding the symptoms and treatments that make the most sense based on their goals and values. Managing symptoms can be complicated and difficult. In research by Wolfe and colleagues, parents reported that 89% of children who died of cancer suffered a lot or a great deal from at least one symptom in the last month of life.[6] In a nationwide study in Sweden, parents of children who died of malignancies reported that pain in particular had a profound impact on their children.[102] Not surprisingly parents are quite distressed by these symptoms, especially changes in behavior and appearance, pain, weakness, fatigue, and dyspnea.[103]

Importantly there is also evidence of progress. A more recent study by Wolfe and associates documented less suffering from pain and dyspnea near death for children who died in the years after their initial study.[4] Thus a culture of awareness and attention to symptoms as well as intensive efforts at management may be able to mitigate the suffering children experience at the end of life.

Many of the symptoms we describe are addressed in detail in Chapter 71, “Symptom Management in the Child with Cancer.” We have therefore limited our discussion to management of common symptoms in the setting of more advanced illness. Medications used in managing common symptoms are listed in Table 70-3.

Pain

Pain should be considered a medical emergency; over 80% of children with advanced cancer experience pain.[6,104] Pain affects not only the physical being but also the emotional and spiritual being. Often pain is accompanied by anxiety and emotional or spiritual distress. It is important to address each coexisting or contributing factor to pain. Parents often express extreme helplessness and distress when the child is suffering in pain.

The child’s report of pain is an essential aspect of assessment.[105] Reliable scales that are consistent in the hospital and home are available, but assessment can be challenging, particularly with the nonverbal child. A knowledge of the child’s usual behaviors and previous experience with pain management and with children with similar diagnoses can be helpful.[106] Tailored assessment tools can allow parents to equate behaviors with comfort or pain on an individualized rating scale.[107,108]

Treatment of pain should be followed by assessment for effective relief. The current WHO pain guidelines

TABLE 70-3 Medication Guidelines for Symptom Management

Symptom	Medication	Dosage	Comment
Anorexia	Megestrol acetate	100 mg PO bid; if no effect in 2 wk, double dose to 200 mg bid	Use only in children >10 yr
	Dronabinol	2.5-5 mg/m^2/dose q4h	Use only in children >6 yr; contraindicated in depression
	Dexamethasone	0.3 mg/kg/day PO/IV	Use only in children >2 yr
	Cyproheptadine	0.25 mg/kg/day divided twice daily; age-dependent maximum daily dose: ≤6 yr: 12 mg/day; 7-14 yr: 16 mg/day; ≥15 yr: 32 mg/day	
Agitation	Haloperidol	0.01 mg/kg PO tid prn; for acute onset: 0.025-.05 mg/kg PO; may repeat 0.025 mg/kg in 1 hour prn	
Anxiety	Fluvoxamine	25 mg/day; may increase by 25 mg every 4-7 days up to 200 mg/day	Rarely can worsen depression or cause suicidality
Constipation	Glycerin suppository	One suppository PR qd	
	Lactulose	5-10 mL q2h until stools	
	Polyethylene glycol (MiraLax)	0.8 g/kg/day PO; maximum dose 17 g/day PO	Always dissolve dose in 4-8 oz of liquid
	Children's Senokot liquid	2-6 yr: 2.5-3.75 mL qd 6-12 yr: 5-7.5 mL qd	
	Pediatric Fleets enema	One PR qd prn	
	Methylnaltrexone	0.15 mg/kg SQ every other day prn	
Depression	Fluvoxamine	25 mg/day; may increase by 25 mg every 4-7 days up to 200 mg/day	Rarely can worsen depression or cause suicidality
	Methylphenidate	5 mg orally in the morning and at noon	Not recommended for children <6 yr
Dyspnea	Morphine sulfate immediate release	0.1 mg/kg PO q1-4h	Starting dose, no ceiling
	Lorazepam	Starting dose 0.025-0.1 mg/kg PO/IV q4h Maximum dose: 0.5 mg/kg	
Fatigue	Methylphenidate	5 mg orally in the morning and at noon	Not recommended for children <6 yr
Fever	Acetaminophen	15 mg/kg PO q4h	
	Ibuprofen	10 mg/kg PO q6-8h	
Insomnia	Melatonin	3 to 5 mg given 3 to 4 hours before an imposed sleep period	
	Trazodone	0.75-1 mg/kg PO at bedtime	Not recommended in children <10 years of age
	Nortriptyline	0.1 mg/kg PO at bedtime	
Nausea and vomiting			
Mild-moderate	Diphenhydramine	1 mg/kg PO q6-8h prn	
	Metoclopramide	0.25 mg/kg PO q8h prn	
Severe	Ondansetron	0.15 mg/kg PO q8h prn	
	Dexamethasone	0.3 mg/kg/day PO/IV	Maximum dose 10 mg/kg/day PO/IV
	Lorazepam	0.025-0.1 mg/kg q8h prn	Maximum 3 mg/day
Pruritus	Diphenhydramine	1 mg/kg PO/IV q4h prn	
	Hydroxyzine	0.5 mg/kg PO q8h prn	
	Hydrocortisone 1% cream	q6-8h	

Continued on following page

TABLE 70-3 Medication Guidelines for Symptom Management (Continued)

Symptom	Medication	Dosage	Comment
Pain			
Mild pain	Acetaminophen	15 mg/kg PO q4h prn or around the clock	Available in 160 mg/5 mL suspension or 80 mg/mL
Moderate to severe pain	Morphine sulfate immediate release	*<6 mo*: 0.1 mg/kg PO q3-4h *>6 mo to 50 kg*: 0.3 mg/kg PO q3-4h for opioid-naïve patient Titrate by 50%-100%/dose Prescribe breakthrough dose of 0.15 mg/kg PO q15-30 min.	
	Time-released morphine (MS Contin, Oramorph, Kadian)	Total daily dose divided by 2 determines q12h dose (approximately 1 mg/kg PO q8 or 12h). Breakthrough dose approximately 10% of the 24 hour total given q1-2h	
	Oxycodone	0.1 mg/kg q3-4h PO	
	Hydromorphone	0.03-0.08 mg/kg q4h PO	
	Fentanyl patch	*2-12 yr:* Do not exceed 15 µg/kg every 72 hours.	
	Methadone	0.1 mg/kg PO/IV bid or tid	No dose adjustments for 72 hours due to long half-life of drug; available in liquid
Adjuvant analgesics	Ibuprofen	10 mg/kg PO q6h	
Bony metastases	Choline magnesium trisalicylate	25 mg/kg PO tid	
Neuropathic pain	Nortriptyline	0.5mg/kg at bedtime	Maximum dose: 150 mg/day
	Gabapentin	*Initial dose:* 10-15 mg/kg/day divided q8h. Titrate if needed to 50 mg/kg/day; not to exceed 2400 mg/day	
Severe visceral distention or bony disease	Prednisone	*Oral solution:* 1 mg/kg/day or bid with food	
Secretions	Scopolamine	1.5-mg patch, apply topically, every 72 hours	
	Glycopyrrolate	0.04-0.1 mg/kg PO q4-8h	
	Hyoscyamine sulfate	*<2 yr:* 4 gtts PO q4h prn (0.125 mg/mL solution) *2-12 yr:* 8 gtts PO q4h prn (0.125 mg/mL solution)	Maximum: 24 gtts/day
Seizures	Lorazepam	0.1 mg/kg PO/SL/PR, may repeat q 15 min × 3 doses 4 mg single dose	Parents should be advised to contact physician if used
	Diazepam rectal gel (Diastat)	*2–5 yr:* 0.2 mg/kg q 15 min × 3 doses *6-11 yr:* 0.3 mg/kg q 15 min × 3 doses *>11 yr:* 0.2 mg/kg q 15 min × 3 doses	Parents should be advised to contact physician if used

recommend the first step for mild pain and the second step for moderate to severe pain.[109,110] This approach suggests moving from weak analgesics, such as acetaminophen, to stronger analgesics such as opioids, although, depending on the presenting pain, strong analgesics may be initiated at the outset. Codeine should no longer be used in children. Although it was previously recommended, prescribing codeine should generally be avoided because of its side effect profile and lack of superiority over nonopioid analgesics. Furthermore, relatively common genetic polymorphisms in the *CYP2D6* gene lead to wide variation in codeine metabolism. Specifically, 10% to 40% of individuals carry polymorphisms causing them to be "poor metabolizers" who cannot convert codeine to its active form, morphine, and therefore are at risk for inadequate pain control; others are "ultrametabolizers" who may even experience respiratory depression from rapid generation of morphine from codeine. It is therefore preferable to use a known amount of the active agent, morphine.[111]

Plans for treatment should be based on the child's report of pain, the type of pain, the history of pain medicine use, and the parent's understanding of the pain and possible treatment options.

The child and parents should be educated about the basic principles of self-report, around-the-clock dosing, and the need for frequent reevaluation. Particularly when a family is facing the end of the child's life, the meaning of a recommendation for a medicine such as morphine sulfate cannot be underestimated.[112-115] Often myths of opioid use need to be explored and education, reassurance, and rationale provided. Using opioids also necessitates the prophylactic treatment of common side effects.

In addition to analgesic agents, there are a variety of adjuvant therapies that may be used to alleviate pain (see Chapter 71, "Symptom Management in Children with Cancer"). Increasingly families are also being encouraged to use nonpharmacologic strategies such as distraction, heat, cold, positioning, and touch. Children may also benefit from acupuncture, hypnosis, Reiki, and guided imagery, particularly if it has been used during the earlier days of treatment.[116-121]

Occasionally a child suffers from severe pain due to malignancy and needs massive opioid infusions. Collins and colleagues found that 6% of children with terminal malignancy were in this category of needing more than 3 mg/kg of morphine dose equivalent per hour. Eight of 12 required epidural or subarachnoid infusion and/or sedation.[122] Children may also experience rapidly escalating symptoms of pain, dyspnea, and or agitation. For these situations it has been beneficial to have templated orders, created by an interdisciplinary group of clinicians, so that sound principles and standard management can be executed at the bedside.[123]

Transitioning a child from the hospital to home with adequate symptom management may pose challenges to the home care system. Strategies such as using concentrated elixir that can be administered buccally, by mouth, or by gastrostomy tube or using transdermal medications such as a fentanyl patch[124,125] may be of benefit. Long-acting agents such as methadone and transdermal fentanyl may be given in conjunction with shorter-acting agents administered intravenously, subcutaneously, or orally. Compounding pharmacies can assist with multiple drug combinations for ease of administration in a variety of preparations. Many home care agencies, including hospice, are able to provide intravenous patient-controlled analgesia in the home setting as well. Finally exploring the potential use of midazolam or propofol infusions with the home care or hospice agency[126] may help determine what can realistically be provided for the child in extreme circumstances at home.

Dyspnea

Similar to pain dyspnea is subjective and can be caused by a multitude of factors. Having the child report the degree of distress associated with dyspnea, using a scale similar to a visual analogue scale for pain, may be helpful.[127] Recommended interventions should be congruent with the child's and family's goals, whether for extending life, relieving suffering, being in the hospital, or remaining at home. For instance if pneumonia is diagnosed, some families may choose parenteral antibiotics, others enteral antibiotics, or others strictly symptom relieving measures, such as treating fever and dyspnea. Diuretics may be given for situations involving fluid overload, and thoracentesis can be considered for pleural effusions, although such interventions may not provide effective palliation in patients with extensive parenchymal disease.[128] Transfusion can be considered if the level of red blood cells is low with the hope of increasing oxygenation potential.

Oxygen is often considered for dyspnea.[129] In a study in adult patients with advanced cancer, Philip and colleagues found that patients reported relief with either room air or oxygen by nasal prongs.[130] Interestingly they also found poor correlation between dyspnea complaints and measured oxygen saturation levels. In the hospital it may be easy to provide oxygen, whereas at home opening a window or providing a fan, to provide facial cooling in the areas subserved by the second and third branches of the trigeminal nerve, in addition to positioning and relaxation techniques, may be useful.

Finally opioid medications intravenously, subcutaneously, or orally can provide relief[131,132] and can be used without hastening death or suppressing respirations. Dyspnea can often be relieved with a lower opioid dose than that used for pain; a starting dose that is 25% to 30% of the opioid dose used for pain is often effective, although the dose should then be titrated to symptom relief. Nebulized opioids have been used, although studies have not confirmed efficacy of this route.[133] Emerging data among adults also suggest that low-dose long-acting opioids may improve symptom relief in chronic dyspnea.[134] In addition anxiety often precedes or follows episodes of dyspnea and may be relieved by benzodiazepines,[135,136] hypnosis, or other relaxation techniques.

Airway Obstruction

Airway obstruction and the resulting "noisy breathing" from excessive secretions and relaxation of oropharyngeal muscles can be very distressing to families. Usually deep suctioning is not helpful and may cause discomfort. Rather explaining that this is a natural result of the physiologic decline and that it is not distressing to the child may be reassuring. Anticholinergics may be used to decrease secretions[137,138] as well as decreasing parenteral or enteral fluids, if they are being given. However overly thickened secretions can lead to airway obstruction and greater distress; thus careful titration of interventions is warranted.

A somewhat different situation occurs when tumor progression causes airway obstruction. In our experience, the respiratory distress that occurs in this situation can be quite difficult to control, even with massive opioid doses. If the child appears to be gasping and uncomfortable despite opioid therapy, then palliative sedation may be warranted. In this case extensive discussions with the family and providers must occur so consensus is reached and it is clear that the goal is to sedate the child and relieve his or her symptoms and not to hasten death.

Gastrointestinal Symptoms

Nausea and Vomiting

Just over half of parents of children who have died of cancer report that nausea and vomiting were present at the end of life, often with significant associated suffering.[6,139,140] Such symptoms sometimes go unrecognized and untreated by physicians,[6,140,141] and even when treatment is offered, efficacy may be limited. Physicians should therefore assess for nausea and vomiting carefully, attend to symptoms promptly, and pay close attention to the efficacy of treatment.

Vomiting is stimulated by the gastrointestinal tract, after local receptor stimulation by obstruction, stasis, or toxins; by the pharynx, due to mucous or mucosal breakdown; by the medullary vomiting center, in response to cortical, gastrointestinal, or chemoreceptor trigger zone stimulation; or by the cortex, in response to elevated intracranial pressure or emotional and sensory stimuli. Chapter 71, "Symptom Management in Children with Cancer," provides further detail on causes of nausea and vomiting in cancer patients. Because the cause may define the most effective therapy, the most likely cause should be considered in evaluation and treatment of the patient.[142]

At end of life chemoreceptor trigger zone stimulation by toxins such as medications (chemotherapeutic agents, antibiotics, and opioids) and metabolic byproducts of uremia or hepatic failure in the blood and cerebrospinal fluid is a particularly common cause of nausea. In addition to effects on the chemoreceptor trigger zone, opioids induce nausea by decreasing gut motility and thereby causing gastroparesis and constipation. Patients may particularly experience nausea and vomiting after dose escalation, but this typically resolves after 3 to 4 days at a stable dose.[136] Opioid-induced nausea and vomiting are usually responsive to antiemetic therapy, especially with 5-hydroxytryptamine antagonists.[136,143,144]

Another important cause of nausea and vomiting in the end-of-life period is bowel obstruction, which deserves particular consideration in patients with abdominal tumors. Management of obstruction is discussed later in this chapter.

Refractory nausea and vomiting in the end-of-life setting have been effectively treated with antipsychotics such as olanzapine[145] and haloperidol. Also of note dexamethasone may have limited efficacy against nausea and vomiting in the end-of-life setting,[146] in contrast to its efficacy with chemotherapy-induced nausea, unless specific corticosteroid-responsive causes such as increased intracranial pressure or bowel obstruction are present. Finally because sights, smells, and the child's emotional state can contribute to nausea, management of distress and any environmental triggers should be considered. Nonpharmacologic therapies such as hypnosis and acupuncture may also be effective.

Constipation

Constipation is a common cause of pain and distress at the end of life,[6,139,140] particularly owing to opioid use for pain. Opioids cause constipation by decreasing colonic motility and secretions and by increasing fluid absorption in the colon. Preventive measures should always be considered at the time of initiation of opioids, with an osmotic and motility agent typically prescribed at initiation. Although many opioid-related side effects tend to decrease over time, constipation tends to remain a problem throughout the period of opioid use.[136]

Other important causes of constipation in the end-of-life care period are decreased patient mobility and decreased oral fluid and nutritional intake.[147] In addition cord compression and bowel obstruction due to intraabdominal tumor should be considered as possible causes.

Unless evaluation reveals an underlying cause such as bowel obstruction[148] or cord compression, therapy should be similar to that used for any child with cancer, regardless of phase of life. Because fluid intake is often limited at the end of life, however, fiber supplementation is not generally useful and can sometimes increase constipation. Similarly stool softeners alone are often inadequate and should instead be replaced by or combined with osmotic agents or stimulants.

For opioid-induced constipation, subcutaneous methylnaltrexone can also be used to relieve constipation. About half of patients will experience laxation after the first dose,[149] and subsequent doses can be given every other day as needed. Despite properties as a mu opioid receptor antagonist, methylnaltrexone has not been found to precipitate pain or withdrawal.[149]

Bowel Obstruction

Intestinal obstruction, such as from an abdominal tumor, is an important cause of refractory nausea and vomiting in the end-of-life care period.[142] Goals of care and the patient's quality of life may guide the choice of treatment. Therapeutic surgical options include bypass of the intestinal obstruction or placement of a venting gastrostomy tube. However nonsurgical alternatives exist for patients who wish to avoid surgery or who have limited ability to tolerate invasive measures.[150] Options for medical management include corticosteroids, which can be useful in relieving obstruction,[151] and octreotide, which can markedly decrease nausea and vomiting by reducing gastrointestinal secretions.[152] Octreotide can be administered subcutaneously and can be used in the outpatient setting if desired. The combination of morphine, scopolamine, and haloperidol has also been used to relieve cramping and nausea and vomiting.

Anorexia and Cachexia

Cachexia is a common finding in patients with advanced cancer. Poor nutritional intake and increased metabolic demands related to cancer appear to be its primary underlying causes. Mechanisms for increased catabolism, including lipolysis and proteolysis, are complex and likely mediated in part by cytokines.[153-155]

Anorexia compounds the problem. This too is mediated by a number of factors, including gastrointestinal (nausea, constipation, mucositis, dysphagia), other physical (pain), medication-related (impaired taste, decreased hunger), and psychological (depression) factors. Often multiple factors contribute to anorexia in any patient, and treatment should be directed at the individual causes when such causes can be discerned.[154,155]

Plans for care should include assessment of the meaning of this syndrome to individual patients and families. Some children and families will not be significantly bothered by anorexia and cachexia, but other children and families will find wasting to be extremely distressing, conjuring up the concern that the child is starving to death. Although severe cancer-related wasting is associated with poor outcomes in adult cancer patients,[156] increased nutrition is not enough to reverse this process.[157,158] Physicians may be able to address concerns about starvation by explaining that the cancer itself may be responsible for this condition and that increased nutritional intake often cannot halt this process. Goals for management should instead focus on symptoms, such as nausea or constipation, associated with this process. Another important goal is the maintenance of the child's level of function.[159]

Treatment of any underlying causes including associated psychological and spiritual issues should be a first step in management. Additional options such as enteral or parenteral[160] nutrition can be considered in light of overall goals of care and the efficacy of treatment for underlying causes. If the family wishes to institute artificial nutrition, it can be helpful to discuss the fact that, as the child's cancer progresses, there may be some point at which supplemental nutrition is no longer providing significant benefits relative to its actual or potential harms. The family and physician may wish over time to reassess the degree to which supplemental nutrition is meeting the goals of care, with the thought that, at some point, discontinuation of supplemental nutrition may make the most sense for the child. Discussion of this issue with families at the time of institution of supplemental nutrition may make reconsideration of this intervention less distressing for families as the child's illness progresses.

Pharmacologic therapeutic options include corticosteroids, which can increase appetite and nutritional intake. Their effect tends to wane after 4 weeks. Cyproheptadine is a safe and effective way to promote weight gain in children with cancer.[161] Cannabinoids such as dronabinol can also increase appetite, as can megestrol acetate.[162] Because megestrol acetate is associated with severe adrenal suppression in children with cancer,[163] it should be used with caution; some have recommended routine corticosteroid replacement for children on megestrol.[163]

Nutrition and Hydration

Near the end of life, fluid and nutritional needs diminish. Because parents often identify provision of nutrition as one of their important roles, physicians should prepare parents for the expected decrease in fluid and nutritional needs as the end of life approaches. Preparation for decreased urine output, as a manifestation of waning perfusion rather than of dehydration, can also be helpful.

Most studies suggest that nutrition and hydration can be withheld or limited in the end of life period without causing suffering.[164-166] In fact continued feeding via gastrostomy or nasogastric tube may be associated with abdominal discomfort or nausea when the child is in the last stages of life. In a study of bereaved parents who had made decisions to forgo artificial nutrition and hydration for their children, parents perceived deaths to be peaceful and comfortable.[167] Many of these parents chose to forgo artificial nutrition and hydration when the child developed feeding intolerance, suggesting that continued artificial nutrition may have increased discomfort.

One study of terminally ill adult cancer patients, however, suggests that some degree of parenteral hydration may improve symptoms associated with dehydration.[168] Even in this study, limited volumes of parenteral fluid were sufficient to improve symptoms. Parenteral hydration also has the potential to affect other choices about care, such as the location in which families feel most comfortable receiving care, the need for medical services at the end of life, and the need for intravenous or subcutaneous access.

When the choice is made not to provide supplemental hydration or nutrition at the end of life, it is helpful to pay close attention to symptoms of dehydration, hunger, or thirst, with the goal of treating any symptoms that arise. Often noninvasive measures such as moistening the lips or providing small tastes of food or fluid are enough to provide comfort.

Fatigue

Fatigue shapes the types of activities that children with life-limiting illnesses choose to participate in and has the potential to significantly diminish a child's quality of life.[169] Parents consider fatigue to be the most common symptom in the last month of life and the course of greatest distress for dying children.[6,170] Unfortunately this symptom is also the least likely to be treated.[6]

In general fatigue is a multidimensional symptom with both physical elements (muscle weakness, decreased energy) and cognitive or affective elements (difficulty concentrating, maintaining attention, lack of motivation and interest).[171] In a retrospective study of children who died of cancer, parents reported that 96% of children experienced fatigue in the last month of life. Nausea and vomiting, anorexia, and fear were other symptoms independently associated with fatigue.[172]

Younger children and adolescents with cancer define fatigue differently; younger children emphasize the physical aspects of the symptom, whereas adolescents describe multiple dimensions and distinguish between mental and physical fatigue.[173] Parents of children with cancer note that physical and emotional dimensions of fatigue create significant disruptions for the entire family.[174] Parents describe mood changes in the child and also report delays around the household and family activities because of the need to accommodate the fatigued child.[174] Fatigue also tends to limit children who wish to attend school until the very end of the illness, rather than receive private tutoring from a teacher in the hospital.[169] For children who remain in the hospital, fatigue also impacts cognitive function and mood due to interrupted sleep patterns that are mostly a result of frequent awakenings throughout the night and daytime hours.[175]

Opioid analgesics contribute to diminished levels of energy as well as a decreased ability to concentrate in children with advanced disease.[169] Coexisting or contributing factors include anemia, infection, pain, depression, and anxiety.[171,176] Assessment instruments commonly utilized to assess fatigue in cancer patients measure severity, onset, course, duration, and distress and concurrently assess other correlated symptoms, yet these assessment tools are not widely used. Furthermore the development of more sensitive instrumentation could assist practitioners in conducting a more comprehensive assessment of fatigue and, thus, provide more effective treatment of this symptom.[177]

Fatigue can seriously affect pediatric quality of life.[169] Multimodal approaches to treatment may be most effective; treatment of anxiety, depression, and sleep disturbance can also mitigate fatigue. Psychostimulants such as methylphenidate can be used to increase wakefulness, particularly when patients have opioid-related somnolence,[178] although they have not been formally evaluated in children. Because methylphenidate has a short duration of action, patients can control the timing of doses to coincide with important events during the day, such as time with family and friends. Blood transfusions, exercise programs (including physiotherapy),[179] psychosocial interventions, acupuncture, rest and relaxation (including playing/socializing), and nutrition and hydration counseling can also help alleviate fatigue.[171,174,180] A qualitative study conducted by Hinds and colleagues[173] reported differing views regarding successful fatigue interventions among patients, parents, and staff: whereas parents and staff considered themselves the primary responders to the child's fatigue and source of alleviation, patients stated rest and distraction as their first choice for alleviating symptoms of fatigue.

Psychological Symptoms

Psychological symptoms (including worrying, sadness, nervousness, and irritability) are among the most common symptoms experienced by children with cancer.[181,182] Some authors have reported that children with cancer as young as 7 years "can report clinically relevant and consistent information about their symptom experience" including psychological symptoms.[181(p 14)] Through interviews with children with life-threatening illness, Woodgate and colleagues[183] have identified a symptom experience described by children as: "I am hurting … My heart is sad." Children may have difficulty distinguishing between such symptoms, instead experiencing them as more of an "overall state," such as "experiences that cause … mental distress or suffering … from feeling sick to being scared."[183(p 811)] In adult studies of cancer patients, the notion of neuropsychological symptom clusters (including depressive symptoms, cognitive disturbance, fatigue, sleep disturbance, and pain) may help shed light on the mechanisms behind these symptoms. It is hypothesized that proinflammatory cytokines may underlie the first stage of development of these symptoms; however, more research is needed to fully understand the role of these cytokines and how this information can be used to effectively treat this cluster of symptoms.[184] This phenomenon of a "cluster" of symptoms is also noted in quantitative studies in which children reported high levels of symptom distress, suggesting an "interplay between psychological and physical symptoms," especially between psychological symptoms and the physical symptom of pain.[182] Additionally when disease advances, it may be challenging for children to discuss with their loved ones and with the health care team some of the emotional issues that arise.

Depression

Children with life-threatening illness have been reported to experience symptoms of depression and may also meet diagnostic criteria for clinical depression. Gothelf found that 16 of 63 adolescents with cancer (25.4%) met the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV) criteria for major depressive disorder.[185] Children older than 12 years, with a diagnosis of acute lymphocytic leukemia, receiving opiate analgesics, or undergoing radiation therapy were all significantly more likely to receive antidepressant medication.[186] Adolescents with higher levels of self-reported depression and lower levels of self-esteem had higher rates of nonadherence to medication; these same teens had lower rates of survival at a 6-year follow up.[187] Collins and colleagues found that roughly 36% of 159 children with cancer between the ages of 10 and 18 reported "feeling sad"; of this group, 17.5% rated its frequency as "a lot to almost always," 59.6% rated its intensity as "moderate to very severe," and 39.5% rated the distress it caused as "quite a bit to very much."[182]

In a younger cohort of children (ages 7 to 12) with cancer, Collins and colleagues[181] determined that 10.1% of the children surveyed reported feeling sad. Of this group, 53% reported feeling sad "a medium amount to almost all the time" on a scale of frequency, 60% reported feeling sad "a medium amount to a lot" on a scale of intensity, and 50% reported their sadness causing "a medium amount to very much" distress.[181] A slightly different story unfolds when Dejong and colleagues conducted a review of studies on depression in pediatric cancer published between 1980 and 2004. The majority of studies reviewed was cross-sectional and conducted, at the most, 5 years after diagnosis. In almost all the studies either no significant differences between depression rates in children with cancer and normal control subjects or significantly lower depression scores among the cancer group were found.[188]

There is mixed evidence that rates of sadness in children with cancer increase as disease advances. Parents have reported that a significant portion (up to 65%) of their children experience sadness during the terminal phase[139,189] and that sadness was the psychological symptom their child experienced most during the child's physical decline.[189] The well-being of children who died between the ages of 9 and 15 years was moderately or severely affected by depression, although similar results were not found among children who died before the age of 4 years.[139]

Risk factors for depression in children with cancer include parental depression and perceived stress and social support; age and illness severity are not consistently associated with depression.[188] However variation in findings across studies may be attributed to factors such as having multiple informants about the child's symptoms. Another confound in conducting accurate assessments of depression relate to the presence of other cancer symptoms or to the medications being taken to alleviate these symptoms, which may exacerbate or mask the symptoms of depression.[190]

Anxiety

Anxiety appears to be quite common in children with life-threatening illnesses.[181,182] In a sample of 149 children between the ages of 7 and 12, 20.1% reported feeling "worry."[181] Of those children, 43% experienced it a "medium amount to a lot" (intensity), 43% experienced it "a medium amount to almost all the time" (frequency), and 30% reported that it caused them "a medium amount to very much" distress. Among 160 older children with cancer,[182] 35.4% reported feeling "worry." Of these children, 66.1% reported that worry was "moderate to very severe," 28.6% reported a frequency between "a lot and almost always," and 27.2% reported the worry caused "quite a bit to very much" distress.

In children with advanced disease, levels of anxiety have been described by parents and health care providers. Researchers studied the medical records of 28 children who died of cancer to understand their end-of-life experiences; 53.6% of the children were documented as experiencing anxiety.[140] In a separate study of 164 symptom assessments collected in the last month of life, 50.0% of children reported "no problem" with anxiety/depression, 27.4% reported a "minor problem," and 17.7% reported a "major problem."[190] Anxiety was found to significantly influence the prevalence of pain.[191] Additionally exposure to physical pain early in life and/or a history of frequent painful medical procedures is associated with fear and anxiety during successive medical procedures, and, in turn, may have implications for future medical nonadherence and other related problems.[192] In the documentation of the symptom experiences of 30 children who died of cancer, worrying and nervousness were two of three symptoms "for which the proportion of children suffering a high level of distress ('quite a bit' to 'very much') was more than 50%."[170(pp 597–598)]

Parents of children who died of cancer were surveyed about their child's symptom experiences during the last month of life and reported, that among other symptoms, their child's sense of well-being was moderately or severely affected by anxiety.[139] Children older than 9 years were reported to be more troubled by anxiety than younger children.[139]

Qualitatively, children have described anxiety and fear together: "I am scared … I don't know what is going to happen to me."[193(p 811)]; often children and families experienced a fear so strong that they could "not focus their thoughts on anything but the cancer and [it paralyzed] children and families from participating in life."[193(p 811)] In children undergoing cancer treatment, anxiety has been commonly linked to the experience of nausea, vomiting, insomnia, nightmares, and rashes. Younger children may act out behaviorally (kicking, fighting).[194] In children with advanced disease, children who identified themselves as feeling "scared" explained that the feeling was often the result of "painful treatments or procedures, experiencing unexpected and new symptoms, and experiencing feelings that there was a greater chance for relapse or death … sometimes the fear experienced by children would be so great this led them to not to talk about the symptom(s) or event(s) that caused them to experience such intense fear and anxiety."[193(p 811)] Parents have described how they handled the fear that their children with cancer experience and note that they dealt with their child's fear by providing a sense of reassurance and security for their child up until the point when they needed to reprioritize their energies on their child's physical health rather than assuage their fears.[195]

Treatment of Depression and Anxiety

Pain, anxiety, distress, and suffering in children with advanced disease are interrelated; thus, providing relief for each of these symptoms is important. Given this reality, depression and anxiety, especially as they relate to other symptoms such as pain, should be treated simultaneously. Depression and anxiety screening programs[196,197] have been documented as operating successfully in oncology outpatient settings and should be adopted as standard practice to the continuum of pediatric care in all ages.

When treating depression and/or depressive symptoms of children in palliative care, a combination of medication and psychosocial therapies is optimal. Fluvoxamine and other types of serotonin reuptake inhibitors may be effective for those children with cancer who also exhibit symptoms of depression and anxiety. In one study of adolescents receiving chemotherapy for advanced cancer, 25.4% of those given fluvoxamine experienced a significant decrease in the somatic and nonsomatic symptoms of major depressive disorder with few side effects.[185] Methylphenidate also has antidepressant properties and may have a more rapid onset of antidepressant effects than other agents.[198] Other antidepressants may also be effective, as may counseling or psychotherapy or, ideally, a combination of medications and psychotherapy when indicated.

In contrast benzodiazepines in isolation are believed to be overused for chronic anxiety. Although medications can be effective in palliative care, therapeutic interventions that address a child's anxiety must be tailored to his or her condition, age, and temperament.[199] In children undergoing cancer treatment as well as at the terminal phases of the disease, supportive therapies such as hypnosis appear to be beneficial.[200,201] Pretend play has been suggested for younger children undergoing cancer treatment,[121] whereas telehealth[202] and virtual reality[203] technologies are on the cutting edge of providing effective forums to provide cost-efficient and convenient methods of support for diverse age groups of pediatric patients and their families.

Sleep Disturbance

Sleep disturbance in children who are critically ill typically takes the form of insomnia-type symptoms (involving difficulties in falling asleep, trouble staying asleep, early-morning awakening, complaints of nonrestorative sleep) and/or periods of too much sleep. When Goldman and colleagues[191] surveyed the records of children with terminal cancer, the prevalence of children who reported that too much sleep was a problem almost doubled between the point of entry into the study ("palliative phase") to the last month of life.

Data on the quality of sleep of children with critical illness found that children infected with human immunodeficiency virus slept approximately 1 hour less than healthy children, had more nightmares, and had more general sleep problems.[204] Children with serious illness [205] also slept significantly less on nights when they were experiencing pain, compared with nights that were pain free, and "reported poor sleep on an average of 43% percent of days with pain and 3% of days without pain."[206]

Predictors of sleep disturbance among cancer patients include pain, breathing difficulty, headaches, hot flashes, limb movements, frequent urination, nausea, and vomiting.[207] Patients who received greater amounts of radiation had poorer sleep.[208] In a study of adolescents with chronic pain, the investigators found a correlation between more frequent pain and daytime sleepiness and longer-lasting pain and later bedtimes; furthermore, sleep/wake problems (irregular sleep habits, hard time falling asleep or waking up) were associated with reduced social/emotional well-being.[211]

Psychological consequences of impaired sleep include feelings of fatigue, impaired daytime functioning, mood disturbances,[210] as well as an negative impact on quality of life, ability to cope, and perception of illness severity.[207] Cancer patients with sleep disturbances also reported high correlations between difficulty falling asleep and fatigue, early awakening and fatigue, and difficulty falling asleep and anxiety. Study results also support the idea that depression, anxiety, and sleep disturbances are related as are cancer-related pain, fatigue, and sleep disturbances.[211,212]

Treatments for problems with sleep include pharmacologic and nonpharmacologic modalities. Pharmacologic treatments include melatonin,[213] the tetracyclic antidepressant trazodone and the tricyclic antidepressants,[210] and antipsychotics (especially for cancer patients with delirium).[207] Psychological and behavioral interventions for sleep disturbance include stimulus control, sleep restriction, sleep education, relaxation training, and combinations of the aforementioned therapies.[210] In cases in which sleep problems are linked to symptoms or correlated with a disorder, treatment of the underlying condition may improve the sleep problems.

Anemia and Bleeding

Decisions about treatment of anemia should center on the child's quality of life and the expectations of the family and providers. For a child whose major complaint is fatigue, significant dizziness, tachycardia or dyspnea, a red blood cell transfusion may add to quality of life.[214] For some children and families, however, the need to travel to a center and spend half a day for associated medical care may make transfusions less desirable.

Fear of profuse bleeding in the setting of thrombocytopenia at the end of life is worrisome for providers and family members. As with red cells, platelet transfusions are not possible in the home setting; therefore careful planning and consideration are necessary so as not to disrupt the child's last days. Families may tolerate only treating symptomatic bleeding or may choose prophylactic scheduling of transfusions at a clinic or nearby hospital.[215] When children are at high risk for bleeding at home, parents and providers may want to develop a plan that minimizes distress to the child if this should occur. For example, ways to apply pressure for a nosebleed or having dark-colored linens on hand may be recommended in this situation.

Mucosal bleeding can sometimes be controlled with less invasive measures.[216] For example, aminocaproic acid can be used orally or intravenously to inhibit fibrinolysis.[217] Nausea is a common side effect, and aminocaproic acid should be avoided in patients who have hematuria. Topical options include fibrin sealants.[217] The tannins present in black teas can also help to stop bleeding. At home, patients can wet a tea bag with cool water and press it onto bleeding gums.

Fever and Infection

Parents of children with cancer are well aware of the consequences of fever and neutropenia during the child's treatment course. At the end of life, it may be appropriate to think about the role of antibiotics in a different way. Fevers may be due to infection; however, they may be due to the underlying disease. If a fever and associated symptoms can be ameliorated with acetaminophen and other simple measures, this may be most beneficial to the child. Other families may feel more comfortable with a course of oral or parenteral antibiotics, whether the child is an inpatient or outpatient. If this is the case, it may be helpful to plan for a time-limited course, after which antibiotics may be discontinued if no infection has been detected. Over time, parents who prefer antibiotic therapy may become more comfortable with only antipyretic treatment if they see that their child can tolerate this management strategy. Meeting with parents and the child to determine what investigative measures and treatment fit with their family goals will help to determine provider recommendations.[218]

Central Nervous System Symptoms

Seizures

Although seizures tend to be associated with limited suffering for the patient, parents often find seizures to be highly distressing at the end of life. Seizures may occur near the end of life as a result of central nervous system disease, electrolyte abnormalities, fever, or hypoxia. For any patient at home and deemed to be at risk for seizures, rectal diazepam should be available. At times seizure prophylaxis with an antiepileptic agent or benzodiazepine may also be desirable, especially if a patient is at high risk.

Increased Intracranial Pressure

Children with intracranial tumors are at risk for experiencing symptoms of increased intracranial pressure as the disease progresses. Common signs and symptoms include headache, vomiting, and somnolence. Although invasive therapies, such as surgical debulking or ventricular shunting, can be considered, the efficacy of such treatments may not be enduring in the end-of-life setting; tumor growth can quickly block a shunt or lead to recurrence of elevated pressure. Administration of dexamethasone can be effective in alleviating symptoms, and the dosing can be titrated as new symptoms arise or if initial symptoms wane. Dexamethasone-associated side effects, including mood changes, cushingoid appearance, and hunger with subsequent weight gain can be a source of distress to patients, and such side effects should therefore be part of ongoing discussion about dose titration. Radiation therapy may also be considered to decrease tumor size and thereby decrease symptoms at least temporarily.

Spinal Cord Compression

Spinal cord compression is relatively uncommon in the end-of-life setting for children with cancer, but it has the potential to severely impact quality of life at the end of life. Early diagnosis and management maximizes the chances of preservation of function.[219] Presenting symptoms include sensory and motor changes as well as bowel and bladder function abnormalities. Prompt imaging, typically with magnetic resonance imaging, can confirm the diagnosis. Dexamethasone can be used to decrease edema at the site of compression, thereby reducing symptoms and preserving neurologic function.[220] A local intervention such as neurosurgical intervention or radiation therapy is the mainstay of treatment, because decompression surgery plus radiation therapy increases the chances of recovery to ambulation.[221] However the specific intervention recommended should take the patient's overall functional status and goals of care into consideration.

Swallowing Impairment

Patients with brainstem involvement of a central nervous system tumor may develop swallowing impairment as one manifestation of disease progression. Such impairment has important implications for nutrition and hydration and may place patients at risk for aspiration pneumonia. Symptoms of coughing or choking when eating or drinking should be regarded as signs of aspiration and evaluated carefully. A swallowing study can establish which consistencies of liquids and solids the patient can tolerate without aspirating. If thin liquids cannot be tolerated, then additives can be used to thicken liquids until they are of tolerable consistency.

Some patients are unable to tolerate adequate nutrition and hydration without a significant risk for aspiration. A trial of a nasogastric tube may be a short-term option, or gastrostomy tube placement can allow long-term sustenance while minimizing food-related aspiration risks. This choice may be most appropriate in patients who are expected to live and to have a reasonable quality of life for some time. Even with a gastrostomy tube, patients remain at risk for aspiration of oropharyngeal secretions. Pharmacologic drying of secretions can offer some help, but most patients remain at risk for aspiration pneumonia. Chemical pneumonitis is also a risk in patients with reflux, and so acid control may also be beneficial.

For some families, placement and use of a gastrostomy tube may not be consistent with a goal of minimizing procedures or risks as opposed to allowing a more natural end of life to unfold. Such families may choose to either limit nutrition and hydration or to continue to provide oral nutrition and hydration despite the inherent risks. When eating provides significant pleasure to the patient, choosing to maintain oral feeding or even continuing to offer "tastes" may positively impact quality of life. For ease some families may choose to use a gastrostomy tube for nutrition and medication administration. Such decisions should be made with sensitivity to the role of parents in providing sustenance for their children and the social interaction inherent in meal time.

WHEN DEATH IS IMMINENT

Escalating Symptoms

For children with chronic conditions and progressive disease, escalating symptoms may occur over days, hours, or minutes. Ideally family goals are known and interventions can be recommended that are consistent.[79] A palliative care team often can assist the primary providers by anticipating what interventions are likely to be the most helpful and to cause the least suffering and in strategizing about how to carry out plans for care. It may be helpful to have an emergency symptom management plan (including pharmacologic and nonpharmacologic interventions) in place to initiate during an inpatient admission or at home. This process facilitates efforts of all involved to anticipate and proactively manage physical and emotional symptoms.

Families need to be reassured that there is no "right" place to be as the child nears end of life. Instead, families should choose what best meets the needs of the child and whole family. Homecare services vary widely between regions and countries.[87,222,223] Hospitals may have the advantage of multiple providers, quicker access to therapies, and even a special room such as a "comfort corner," but it is never "home."

For a patient experiencing extreme distress in the hospital, one strategy is to have algorithms or template orders in place for intravenous administration of medications with starting doses and resources to be accessed. Such an escalating situation for a child at our institution prompted nurses, physicians and pharmacists to develop a set of orders for management of escalating pain, dyspnea or agitation, using morphine, fentanyl, or hydromorphone, to improve care in these relatively rare but highly demanding cases.[123] Some general recommendations for rapid escalation include the following:[123]

- Bedside titration when symptoms arise, with intravenous bolus dosing every 10 to 15 minutes until pain is relieved
- Initial bolus dose of 10% of the 24-hour intravenous morphine dose for patients already on opioids
- Increase of intravenous bolus dose by 30% to 50% every third dose for unrelieved pain

- Initiation of continuous infusion once pain is relieved, with additional dosing, approximately equivalent to hourly rate, for breakthrough pain
- Increase of hourly intravenous rate and bolus by 30% to 50% when pain is unrelieved by existing regimen

At some institutions, a 24-hour on-call palliative care service or pain treatment service is available for assistance. Often allowing children who are facing the end of life to be directly admitted to their usual inpatient unit, with staff members who know them, will lessen the anxiety of the family and child and allow for faster, individualized care.

Palliative Sedation

Palliative sedation may be considered in rare circumstances. Sedation for refractory symptoms requires pain and palliative care expertise and a trusting relationship with the child and parents of the dying child. It must be clear that it is not the same as euthanasia and is not intended to hasten death, although parents who are desperate to see their child at peace may ask for that. When a child's refractory or unendurable symptoms cannot be managed by the "best standard" with opioids, benzodiazepines, and all other adjuncts, then palliative sedation may be warranted.[224,225]

Palliative sedation has the expressed outcome of relieving patient suffering and is considered only when physical and/or psychological symptoms are refractory to all other reasonable medical and complementary therapies.[226,227] Medications are most commonly started by a continuous infusion and titrated to the effect that the patient and/or parents and medical team have agreed upon. The most common agents used are anxiolytic sedatives, sedating antipsychotics, barbiturates, or general anesthetics.[126,226,228,229] Suggested dosing may be found in *Fast Facts*[230] available at www.eperc.mcw.edu or the *National Hospice and Palliative Care Compendium.*[231]

Before beginning palliative sedation, a frank discussion needs to be held with the family as well as the health care team so that any questions, concerns, or misgivings may be addressed.[232] Staff and/or family members may express ethical concerns that may be addressed by the pain or palliative care team, chaplaincy, or ethics consultation service. Ethical principles, including the "principle of double effect" and "principle of proportionality," justify the use of such measures when the benefits outweigh possible unintended but foreseeable consequences. Allowing for a full discussion of any ethical concerns, as well as the consistent intent to relieve suffering,[232] may be helpful. The patient and/or family and staff need to agree on the symptoms, amount of distress, and reasonable outcomes of interventions. Being certain that the patient and family have had the opportunity to express any final thoughts or feelings while the loved one is awake and conversant may be important to reduce the subsequent potential for regret.

Talking with Parents About What to Expect

Parents usually want to know and often ask what to expect as their child nears death.[16] In particular parents often want to know how to achieve comfort for their child, both with medications and with nonpharmacologic interventions. Once it is clear that there is very little likelihood of the child's clinical situation being stable or improving, families want to know when their child will die. Using parameters of prognosis such as "hours to days," "days to weeks," or "weeks to months" can be helpful because so often more specific prognostication is wrong.

Families want to know what death will look like and what to look for, so that they may be ready and be present at the moment of death. Some may wish to keep cardiac and respiratory monitors turned on to help them be prepared and know when it might be "safe" to leave the bedside, if only momentarily. It may be helpful to describe likely physical changes such as decreased mobility, weakness, loss of interest in eating or drinking, and decreased interest in interacting.[83] Being frank about decreased urine output, cool and mottled extremities, vital sign and breathing changes, respiratory congestion, and decreased level of consciousness in the final days can allow the parents to recognize the situation when it occurs.

At this time, it is important to help families focus on being with their child in whatever way is helpful to the child and family. Highlighting what family members can do for their loved one, for example, a simple hand or foot massage, retelling favorite family stories, playing music, praying, reading poems, and simply being present are examples.

Despite our best efforts, not every death is peaceful. Although assuring families that we will do everything possible to alleviate suffering and allow for a peaceful death, we cannot make promises. Some families interpret this as their child "fighting to the end." Making sure staff is present, listening, and responding to anyone's distress. During such times, it is important to reaffirm the positive role of the parents, siblings, and grandparents throughout the child's life.

Talking about Autopsy

The discussion about autopsy is often dreaded by staff, and sometimes it is avoided altogether, although ideally it is discussed by a trusted caregiver before the death. Some families ask about organ/tissue donation, and autopsy may be discussed similarly. Some families may believe that the child has "been through enough"; however some believe that this is a way to advance science and help other children who may suffer from the same condition. Autopsy may answer some of the questions about disease, cause of death, or side effects of treatments. Tissue or organ donation, including donation to science through autopsy, may be a part of a child's legacy. Studies have shown adults and children are altruistic even when facing death,[233] and so autopsy may be offered as a kind of "gift" to future affected children, to medical science, and to the training of physicians who are seeking cures to diseases. In addition to inviting the family to meet for a bereavement visit, inviting them to review the autopsy results with trusted providers and a pathologist may allow lingering questions or concerns that may be causing parental distress to be explored.[234]

Care of the Child’s Body after Death

After death, whether at home or in the hospital, families often value the opportunity to have time for memory-making activities, family rituals, sharing of stories, and having staff come to pay respect. They may also want to participate in washing or dressing the body. In the hospital, one of the most difficult moments comes when the family leaves the hospital without their child. Having one staff member stay with the body while another accompanies the family to the lobby may be comforting. At home sometimes a parent chooses to carry the body to the hearse rather than have staff remove the body. Again having home care/hospice staff be present through this time may assist the family by bearing witness and holding the sacred space in an unspoken way. Finally, reassuring the family of bereavement follow-up allows them to know that continued contact will occur and is available.

AFTER DEATH

Bereavement Care for Families

Bereavement is a term used to describe the overall experience of family members and friends in the periods before, during, and after the death of a loved one.[235] It includes the unique grief (the emotional/internal process experienced as a result of the loss) that family members and loved ones feel as well as the mourning process (the more external process related to changing one’s environment as a result of the loss) for the loss of a child.[236]

Bereavement begins upon the diagnosis of any pediatric life-limiting condition, because the diagnosis, in itself, signifies a loss of normal life and the beginning of significant emotional and physical adaptations on the part of the family. Health care providers can begin to support the family before the death of the child by helping the family to stay connected with the child, communicate effectively with the child, process the concept of the “appropriate death,” and develop memories. In addition, health care providers may help the family to negotiate the medical system, obtain respite care, and assist with the “prethinking” of the funeral.[237] Having this type of system in place before the death of the child can help the family begin to adapt to life without their child.[238]

The grieving process for families who have just lost a child is typically fraught with the ache of coming to the realization that they will no longer see or be with their child. This process is often layered with a sense of guilt as well—guilt that stems from questioning their treatment decisions, thoughts that they caused the illness, as well as guilt from perhaps giving more attention to the ill child than other siblings.[237] The two-track model of bereavement, described by Rubin,[239,240] can guide interventions in dealing with the grief of family member by first (track one) assessing the individual’s functioning (for example his or her feelings of anxiety, depression, guilt, return to work) and then (track two) assessing the relationship of the individual to the deceased person, even as it continues to evolve and change in meaning over the course of the surviving relative’s life span. Similarly via review of recent literature on parent grief, Davies rejects certain notions that bonds with the deceased individual must be broken for grief to be resolved or to obtain closure. Instead she concludes that “exploring the significance of their children’s lives, as well as the continuing influence they have through continuing bonds, may be regarded as a positive means [of] dealing with bereavement.”[241(p 510)] Others emphasize attempting to understand patterns of individual differences in grieving families and how continuing the bond with the deceased while relinquishing certain ties can be adaptive to the family functioning on a long-term basis.[242]

Spinetta and colleagues measured the after-death (up to 3 years after the death) adaptation of parents whose child had died from cancer. Of 23 sets of parents interviewed, most had “adequately mastered” a return to normal activities, become active and zestful again, become able to confront physical reminders of their child, and had no regret of the past. Other tasks, such as resolving remaining questions and healing relationships with siblings, were found to be more difficult for the bereaved parents.

Four to 6 years after the death of a child due to cancer, bereaved parents were more likely to report depression, low to moderate psychological well-being, and anxiety compared with nonbereaved parents. Overall self-reports of continued grief were associated with more anxiety and depression. The risk for depression and anxiety for bereaved parents resembled that of nonbereaved parents 7 to 9 years after the death of the child; however parents were at an increased risk if their child was 9 years or older at the time of death.[243,244]

Immediate supportive bereavement interventions can take place during end-of-life care. In-depth qualitative interviews with 10 mothers of children who died of a variety of life-limiting illnesses revealed four main needs of the mothers during the end of their children’s’ lives: time with their dying child, space and privacy to be with their dying child, time to be with their child’s body after death, and space and privacy to be with their child’s body after death. Mothers who did not have time, quiet space, and dignity expressed distress and anguish over the unavailability of these things.[245] In a study of 156 bereaved parents, Lichtenthal and colleagues[246] explored how parents brought meaning to the loss of their child. Through qualitative analysis of these parent interviews, *meaning making* was broken down into two themes: (1) sense-making (the use of spirituality and religious beliefs in finding meaning) and (2) benefit-finding (the increased need to offer help and compassion for others’ suffering). The support of *meaning making* for bereaved parents can be a valuable tool for balancing the act of maintaining ties with their deceased child while also facilitating the relinquishing of some ties that may complicate grief.

Shortly after their child’s death, many parents cited that the attendance of members of health care team at their child’s memorial or funeral service tended to be helpful in coping with their loss. Parents also found that formal support groups where they could speak with other parents who had similar experiences, follow-up contact with the health care team to discuss results of the autopsy, contact with the health care team on significant days (e.g., anniversaries of the death, Mother's or Father's Day), and guidance in how to help siblings cope with the loss of a brother or sister proved to be beneficial while they mourned their loss.[247] Other, more long-term, types of supportive care for bereaved families included individual grief counseling for one or both parents, couples counseling, family counseling, and social support groups,[237] including Internet support groups.[248]

Care of Siblings

Siblings of children with cancer are deeply affected by their experiences of the sibling's illness and its effects within the family.[249] Siblings experience profound life changes as a result of the illness and experience intense positive and negative feelings.[250] Bereaved siblings are at increased risk for low self-esteem, have lower levels of personal maturity, and experience more difficulties falling asleep than nonbereaved siblings.[251] In addition the family dynamic and their role within the family are often altered by the illness.[250]

The experiences of bereaved siblings are particularly intense. Their bereavement is often marked by feelings of anger, guilt, jealousy, and sadness.[252] A particular area of distress reported by siblings is a lack of involvement in the dying process.[252] Parents in particular may choose not to involve the sibling closely in the end-of-life period so as to protect them.[253] However it is possible that limited involvement is even more problematic for some siblings than being closely involved in the end-of-life period. Care providers should encourage open communication and allow involvement in care to the extent that siblings wish. Helping parents to understand that such involvement can be healing may be useful.

Care of Staff

Providing care to children with life-limiting illnesses and their families can be one of the most worthwhile acts a health care professional can offer. At the same time providing pediatric palliative care services can place both uniquely physical and emotional demands on the health care team. Pediatric oncologists need to be aware of the impact of these stressors on themselves and colleagues and take the appropriate steps in maintaining both a healthy physical and emotional well-being. Zambrano and associates[254] investigated how general practitioners processed the death of their adult patients. The general practitioners who participated in the study used the metaphor of a "death journey" that involved five different moments that depicted their experience with dying patients: private acknowledgment, communication of prognosis, continuity of care, the moment of death, and looking after the family. A model of self-awareness for grief in caregiving as described here is a positive step in acknowledging the very normal emotions that practitioners experience when caring for sick patients and thus opens the door for self-care and prevention of burnout at each stage of the caregiving process.

Stressors identified by hospice nurses and physicians have included care of patients with intractable symptoms, difficult communication issues, administrative concerns and paperwork, too many patients dying at the same time, the expectation (among family members, other staff, or self-imposed) that all the patient's problems can be fixed, as well as becoming overinvolved in the care of their patients.[255-257] When pediatric residents were asked to rate their personal experiences regarding death, similar emotional stressors such as guilt and feelings of responsibility over the child's death were prevalent.[258]

Self-care can take the form of staff support sessions, educational seminars, as well as mechanisms created within the medical system to relieve professionals of patient service time to restore physical and emotional well-being. Methods for staff support can include regular, confidential debriefing sessions consisting of time for reflection with opportunities for staff to share challenges as well as effective ways for coping with these challenges.[259] These debriefing sessions can either have a specific focus (e.g., processing the death of an individual child) or can have a more general focus that might take into account the day-to-day issues that arise from providing pediatric oncology and palliative care services.[260] Other types of staff support sessions can take the form of annual or semi-annual memorial services to give health care teams a designated day to remember those children they cared for throughout the year.[255,261]

Often a combination approach of providing educational seminars regarding palliative care topics as well as time set aside to discuss and process emotions can be quite effective in gathering a larger crowd of professionals who may not necessarily attend one type or another. For example a combination approach could include a 1-day[262] or several-day death and bereavement retreat for residents to help them achieve the following goals: gain experience in talking about child death with parent; practice being in emotional situations; provide knowledge about autopsy, organ donation, and ministry; provide resources for supporting the family; gain insight into the impact of death on themselves and prevent burnout from stress; and provide resources to better understand the parents' perspective.[263-265]

Sumner suggests opportunities for professional growth for the seasoned professional as well as new providers of pediatric oncology and palliative care services through mentorship programs. This type of program would encourage, for example, a new physician or pediatric oncology provider be partnered with an "expert colleague."[255] The mentor, in turn, may develop the sense of satisfaction of self-efficacy in training a new member of the team in providing pediatric palliative care.

ONGOING CHALLENGES

High-quality palliative care is now an expected standard,[28,80] and Hospice and Palliative Medicine has been recognized as a formal medical subspecialty.[266] The American Academy of Pediatrics set the following as a minimum standard for pediatric palliative care: "Excellence in pediatric palliative care is essential for hospitals and other facilities caring for children. Program development in pediatric palliative care, along with community outreach and public education, must be a priority of tertiary care centers serving children.”[80]

Although the principles of pediatric palliative care have been defined and refined over recent decades, notable challenges remain in all domains of care, including communication, symptom management, coordination of care, and bereavement. The field of pediatric palliative care is still in need of rigorous research efforts, and these efforts should be integrated into curricula across disciplines and at all levels. Further advocacy aimed at creating greater opportunity for children to receive palliative care across care settings is essential.[28]

   This study evaluated the prevalence of symptoms and suffering at the end of life among children with cancer. Many children received aggressive treatment and experienced significant suffering.

7. Bluebond-Langner M, Belasco JB, Goldman A, et al: Understanding parents' approaches to care and treatment of children with cancer when standard therapy has failed. *J Clin Oncol* 25:2414–2419, 2007.

   This ethnographic study evaluated parents' decisions about care for their children with relapsed disease and a poor prognosis. Most parents wished to continue cancer therapy even after standard therapy had failed.

8. Wolfe J, Klar N, Grier HE, et al: Understanding of prognosis among parents of children who died of cancer: impact on treatment goals and integration of palliative care. *JAMA* 284:2469–2475, 2000.

   This study identified delayed parental recognition of a child's poor prognosis relative to physician recognition. Earlier parental recognition of a poor prognosis was associated with a greater use of palliative measures.

9. Murray SA, Kendall M, Boyd K, et al: Illness trajectories and palliative care. *BMJ* 330:1007–1011, 2005.

   This article describes different illness trajectories and the ways that trajectory of illness impacts the use of palliative care.

10. Mack JW, Wolfe J, Grier HE, et al: Communication about prognosis between parents and physicians of children with cancer: parent preferences and the impact of prognostic information. *J Clin Oncol* 24:5265–5270, 2006.

    This study evaluated parent preferences for prognostic information and found that most parents want prognostic information even if they also find it upsetting.

12. Thompson LA, Knapp C, Madden V, et al: Pediatricians' perceptions of and preferred timing for pediatric palliative care. *Pediatrics* 123:e777–e782, 2009.

    This study evaluated pediatricians' beliefs about the optimal timing of palliative care. Most equated palliative care with hospice and referred patients only when there was no possibility of cure.

15. Seecharan GA, Andresen EM, Norris K, et al: Parents' assessment of quality of care and grief following a child's death. *Arch Pediatr Adolesc Med* 158:515–520, 2004.

    This study evaluated the relationship between perceived care quality and experiences with grief after a child's death. Satisfaction with care was generally high despite grief.

16. Mack JW, Hilden JM, Watterson J, et al: Parent and physician perspectives on quality of care at the end of life in children with cancer. *J Clin Oncol* 23:9155–9161, 2005.

    This study evaluated factors associated with parent ratings of the quality of care their child received near death. Physician communication was a primary determinant of quality of care ratings.

17. Hurwitz CA, Duncan J, Wolfe J: Caring for the child with cancer at the close of life: “there are people who make it, and I'm hoping I'm one of them.” *JAMA* 292:2141–2149, 2004.

    This article provides guidance for conversations with children and parents near the end of life, including identifying and supporting goals of care.

21. Hinds P, Drew D, Oakes LL, et al: End-of-life care preferences of pediatric patients with cancer. *J Clin Oncol* 23:9055–9057, 2005.

    Adolescent patients were interviewed after making end-of-life decisions about care; many of their decisions focused on the needs of their loved ones.

23. Hinds PS, Oakes LL, Hicks J, et al: “Trying to be a good parent” as defined by interviews with parents who made phase I, terminal care, and resuscitation decisions for their children. *J Clin Oncol* 27:5979–5985, 2009.

    The researchers evaluated parents' perspectives on end-of-life decision-making for their children and found that many were guided by their feelings about what it means to be a good parent.

24. Renjilian CB, Womer JW, Carroll KW, et al: Parental explicit heuristics in decision-making for children with life-threatening illnesses. *Pediatrics* 131:e566–e572, 2013.

    This study evaluated heuristics used by parents of children with life-threatening illness as they made decisions about care.

26. Wiener L, Zadeh S, Battles H, et al: Allowing adolescents and young adults to plan their end-of-life care. *Pediatrics* 130:897–905, 2012.

    This study describes the development of the Voicing My Choices planning guide for young people with life-threatening illness.

28. Field MJ, Behrman RE; Institute of Medicine (U.S.) Committee on Palliative and End-of-Life Care for Children and Their Families: *When children die: improving palliative and end-of-life care for children and their families*, Washington, DC, 2003, National Academy Press.

    This Institute of Medicine report describes the state of palliative care for children.

30. Himelstein BP, Hilden JM, Boldt AM, et al: Pediatric palliative care. *N Engl J Med* 350:1752–1762, 2004.

    This review describes central issues in pediatric palliative care.

31. Durall A, Zurakowski D, Wolfe J: Barriers to conducting advance care discussions for children with life-threatening conditions. *Pediatrics* 129:e975–e982, 2012.

    This study evaluated clinician perspectives on barriers to advance care planning discussions. Lack of parent understanding of prognosis was perceived as a major barrier.

32. Lyon ME, Jacobs S, Briggs L, et al: Family-centered advance care planning for teens with cancer. *JAMA Pediatr* 167:460–467, 2013.

    These authors offered advance care planning interventions for adolescents with cancer and found that interventions were associated with decisions to limit treatments.

35. Kreicbergs U, Valdimarsdottir U, Onelov E, et al: Talking about death with children who have severe malignant disease. *N Engl J Med* 351:1175–1186, 2004.

    This study found that parents who choose not to talk with their children about the child's imminent death may regret not having done so.

61. Hexem KR, Mollen CJ, Carroll K, et al: How parents of children receiving pediatric palliative care use religion, spirituality, or life philosophy in tough times. *J Palliat Med* 14:39–44, 2011.

    This study found that many parents draw on religion, spirituality, or life philosophy when caring for a child with advanced illness.

71. Bomba PA, Vermilyea D: Integrating POLST into palliative care guidelines: a paradigm shift in advance care planning in oncology. *J Natl Compr Canc Netw* 4:819–829, 2006.

    This article describes the use of POLST (Physician Orders for Life-Sustaining Treatment) in the oncology setting.

88. Tomlinson D, Bartels U, Gammon J, et al: Chemotherapy versus supportive care alone in pediatric palliative care for cancer: comparing the preferences of parents and health care professionals. *Can Med Assoc J* 183:E1252–E1258, 2011.

    This study found that parents are more likely than clinicians to desire aggressive treatment for their children at the end of life.

95. Kang TI, Hexem K, Localio R, et al: The use of palliative chemotherapy in pediatric oncology patients: a national survey of pediatric oncologists. *Pediatr Blood Cancer* 60:88–94, 2013.

    This study describes oncologists' experiences prescribing palliative chemotherapy; 40% of oncologists described prescribing chemotherapy in order to respect parental wishes.

100. Mack JW, Joffe S, Hilden JM, et al: Parents' views of cancer-directed therapy for children with no realistic chance for cure. *J Clin Oncol* 26:4759–4764, 2008.

    This study found that, although many parents chose chemotherapy at the end of life for their own children, not all would recommend it to others, especially if they believed their child had suffered as a result of chemotherapy.

109. Persisting pain in children package: WHO guidelines on the pharmacological treatment of persisting pain in children with medical illnesses. 2012. Accessed August 13, 2013 at <http://whqlibdoc.who.int/publications/2012/9789241548120_Guidelines.pdf>.

    These guidelines offer information about pain treatment for children.

167. Rapoport A, Shaheed J, Newman C, et al: Parental perceptions of forgoing artificial nutrition and hydration during end-of-life care. *Pediatrics* 131:861–869, 2013.

    This qualitative study evaluated parental experiences of forgoing artificial nutrition and hydration at the end of their child's life.

196. Kersun LS, Rourke MT, Mickley M, et al: Screening for depression and anxiety in adolescent cancer patients. *J Pediatr Hematol Oncol* 31:835–839, 2009.

    This study found that adolescents report relatively low levels of anxiety and depression, especially compared with physicians' reports about adolescents.

244. Rosenberg AR, Baker KS, Syrjala K, et al: Systematic review of psychosocial morbidities among bereaved parents of children with cancer. *Pediatr Blood Cancer* 58:503–512, 2012.

    This systematic review summarized findings about psychosocial outcomes among bereaved parents of children with cancer. Parents had increased risks for anxiety, depression, prolonged grief, and poor quality of life.

Progress in understanding the causes of pediatric cancer, as well as advances in cancer-directed therapies, hold great promise for curing and extending the lives of many children diagnosed with cancer. However, as advances in medicine and technology improve the survival of children with life-threatening illnesses, attention to health-related quality of life and progress in symptom management have not kept pace with advances in disease-directed therapies. As a result a population of children exists who are living with cancer and have suboptimally controlled symptoms.

Amelioration of symptoms experienced by a child with cancer does far more than reduce the suffering caused by the troublesome symptoms. Control of physical symptoms may allow attention to be focused on other issues faced by family members who are living with a child's cancer, such as psychosocial concerns or existential distress, and it may allow them to participate in activities and interactions that are important for maximizing quality of life. In fact, symptom burden is highly associated with quality of life in children with cancer[1] and is one of the most significant determinants of quality of life in adolescents and young adults with cancer.[2] In some instances, improved control of symptoms may enhance the delivery of optimal cancer-directed therapy as well. Finally, optimal symptom control throughout the illness trajectory may also shape the child's and family's long-lasting impressions of their experience with cancer.

In many instances, relief from distressing symptoms is possible with a myriad of modalities available today. Pediatric oncologists play a key role in managing symptoms in their patients. Symptom management requires actively partnering with families to assess not only the presence of symptoms but also the impact of uncontrolled symptoms on their daily lives, as well as to implement appropriate symptom-directed interventions. Ideally such attention to symptoms occurs in the context of attention to the child's overall condition so that the impact of symptoms on the child's overall quality of life is appreciated.

The vast majority of children who have cancer experience multiple symptoms that could be ameliorated but are not addressed.[3,4,5,6,7] For example, Collins and colleagues[3] asked 10- to 18-year-old children about the symptoms they experienced during the past week. Symptoms included lack of energy (49%), pain (49%), nausea (45%), lack of appetite (40%), and itching (33%).[3] The prevalence of uncontrolled symptoms in children with cancer is likely to stem from a variety of systemwide causes, including inadequate formal training dedicated to symptom management, a focus on cancer-directed treatment, and time constraints.

In addition, a lack of systematic research in the pediatric population, particularly with regard to non–pain-related symptoms, leads to a lack of evidence or standards on which to base interventions. Many symptom-directed interventions for children at this time are based on extrapolation from adult studies or even individual or anecdotal experiences. Some guidelines exist that are strongly evidence based, such as the National Comprehensive Care Network (NCCN) Guidelines for Pediatric Cancer Pain, which is encouraging.[8] As advances in pediatric oncology extend into the realm of symptom management, additional guidelines for non–pain-related symptoms will become available to help pediatric oncologists attend to their patients' symptoms.

The promising survival rates that have resulted from discoveries in pediatric oncology have led to increasing attention to health-related quality of life and the human costs of cancer care.[9] With such a shift, efforts to understand and ameliorate the myriad of symptoms experienced by children with cancer are likely to be increasingly supported in the coming years.

PAIN

Pain is defined as "an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage."[10] This symptom is the most studied and best understood of all cancer symptoms in adults and children alike. However, despite such attention, pain is often suboptimally controlled.

Families and children confronting cancer often worry about potential pain due to the disease and its treatment. In fact, pain is the most feared problem for children with cancer.[11] To some extent, their concern is justified. For example, Collins and colleagues[3] demonstrated that children with cancer experience multiple symptoms, including pain. Among 160 children ages 10 to 18 years with cancer, pain was the second most common symptom, with a prevalence of 49.1%. In addition, 61.6% reported pain that was moderate to very severe in the 48 hours prior to completing the questionnaire, and 40.9% reported pain that occurred "a lot" to "almost always." Moreover, the pain experienced by children was distressing—"quite a bit" to "very much" in 39.1% of respondents.

Pain control provides a variety of benefits beyond the amelioration of suffering. Prompt pain relief is needed to prevent central sensitization, a centrally mediated hyperexcitability response that may result in escalating pain. Uncontrolled pain also leads to a physiologic stress response with a variety of effects such as altered metabolism and immune function. Control of pain with appropriate analgesia in the perioperative period can reduce some of these effects and prevent complications.[12]

Epidemiology

In general, pain experienced by children with cancer may be caused by a variety of entities, including the disease itself (e.g., tumor invasion of bone, viscera, or the peripheral or central nervous system [CNS] or compression of the spinal cord), treatment (e.g., mucositis, radiation-induced dermatitis, and drug-induced neuropathy) or procedures (e.g., venipuncture, lumbar puncture, and bone marrow aspiration or biopsy, as well as postoperative pain). Authors who performed a cross-sectional analysis of pain in inpatient children with cancer found that the most frequent cause of pain was adverse effects of antitumor therapy.[13] Evidence also indicates that children who have solid tumors outside of the CNS have more pain and higher opioid requirements.[14]

Because the majority of pediatric cancers respond at least initially to treatment, most of the pain that children experience early in the disease trajectory is related to procedures and treatment. Later, if the cancer progresses, pain is more likely to be due to tumor extension. In a series of structured interview surveys conducted by Ljungman and colleagues,[15] 49% of children with cancer experienced pain at diagnosis. Procedure- and treatment-related pain were the most significant types of pain at the start, and although procedure-related pain improved, treatment-related pain did not improve. In addition, measurement of pain intensity was rarely performed.[15]

A significant barrier to pain management in children stems from the fact that research and development of evidence-based practice guidelines in pediatrics lag behind that in adults. The NCCN and World Health Organization (WHO) have developed comprehensive guidelines for managing pain in children with cancer,[16] but in many instances, pain management in children relies on extrapolation from adult data, anecdotal reports, and personal experience.

Children may also experience incidental, non–cancer-related pain. Other pain-inducing disorders such as migraines, recurrent abdominal pain, or injuries seen in the general pediatric population can also occur in children with cancer. These causes of pain unrelated to the cancer diagnosis should always be included in the differential diagnosis of pain in children who have cancer.

Pathophysiology

Nociception is a complex process whereby actual (or potential) tissue damage is perceived as pain by an individual. In many instances pain is a protective mechanism that alerts a person to tissue injury. Nociception may be thought to occur on three levels: peripheral, spinal, and supraspinal (Fig. 71-1). Through transduction, the primary afferent nociceptors, which are thinly myelinated A-delta and unmyelinated C fibers, transmit biochemical changes at the sensory nerve endings that are generated by painful (chemical, thermal, or mechanical) stimuli into electrical signals. Stimulation of such nerve endings in the periphery may be increased or decreased by molecules such as prostaglandins, leukotrienes, bradykinin, and histamine. For example, the bradykinin and histamine that accompany tissue inflammation can directly activate nociceptors, in addition to reducing their threshold and increasing their response to suprathreshold stimulation.[17] The analgesic effect of nonsteroidal antiinflammatory drugs (NSAIDs) lies in their ability to inhibit prostaglandin synthesis and thus desensitize nociceptors.[18]

The electrical signals generated are propagated, or transmitted, to second-order neurons that synapse with sensory nociceptors in the dorsal horn of the spinal cord. Second-order neurons convey signals via ascending tracts in the spinal cord, including the anterolateral spinothalamic tracts, to supraspinal sites that include the brainstem, thalamus, and cortical areas involved in the sensory and affective dimensions of pain.

For example, descending inhibitory pathways from the thalamus and brainstem modulate excitatory transmission through such inhibitory neurotransmitters as serotonin, norepinephrine, and endogenous opioids. Several pharmacologic interventions such as opioids and tricyclic antidepressants (TCAs) exert their analgesic effects through such inhibitory processes at the spinal and supraspinal levels.

Pain is a complex sensory and emotional experience that involves nociception but is modified by a range of contextual and psychological factors. Because the experience of pain is subjective, the degree of tissue injury and therefore nociceptive input does not necessarily correlate with the intensity of pain experienced. Interventions that may reduce the perception of pain include hypnosis and relaxation techniques.

Pain that results from stimulation of intact neurons by impulses reflecting tissue injury or inflammation is called *nociceptive pain*. On the other hand, pain resulting from abnormal excitability of neurons (for example, due to neuronal damage) is called *neuropathic pain*. Even if tissue damage initially accompanied neuropathic pain, neuropathic pain may persist long after the damage has resolved. Nociceptive pain often may be distinguished from neuropathic pain by its characteristics. Neuropathic pain frequently is described as burning or shooting and is often associated with paresthesias or allodynia (i.e., elicitation of pain by normally nonpainful stimuli such as light touch).

Factors Influencing a Child's Experience of Pain

As a subjective experience, many factors have an impact on a child's experience of pain. Recognizing such factors can facilitate an understanding of the pain as it is experienced by the child and facilitate development of an effective pain treatment plan. The experience of pain shapes learning in infancy and throughout life. The neurobiologic mechanisms underlying nociception develop during the third trimester. Specific cortical responses to noxious stimuli can be demonstrated in 32-week preterm infants using evoked potentials or near-infrared spectroscopy. The nature of pain as a conscious experience in young infants remains a subject of speculation and controversy.[19]

Factors influencing the perception and meaning of pain that occurs after infancy are both individual and contextual and include developmental and cognitive factors (e.g., understanding, control, expectation, and relevance) and behavioral and emotional factors (e.g., anxiety, fear, frustration, anger, guilt, and isolation), as well as familiar and cultural factors.[20-22] A variety of other factors including age, gender, pain acceptance, and pain tolerance have been hypothesized to influence pain perception in the pediatric population and have been summarized elsewhere.[23]

Importantly, previous encounters with pain may heighten the experience of subsequent encounters with pain. For example, children newly diagnosed with cancer who had inadequate procedural analgesia when undergoing a first bone marrow aspirate or lumbar puncture had more severe distress during subsequent procedures, even when efficacious pain relief was subsequently provided.[24] This finding highlights the need to provide effective analgesia to prevent both present and future painful experiences.

Assessment

Pain assessment and measurement provide the foundation for addressing pain effectively. Regular assessment of pain may improve pain management[25,26] and should be conducted in a developmentally appropriate manner. When permitted by the child's developmental status, self-report is considered the gold standard in pain assessment. Because self-report can include bias and error, behavioral observations, physiologic changes, and clinician/parental report may be incorporated into the pain assessment. However, these methods also have inherent limitations. For example, tachycardia may reflect fever or intravascular volume depletion rather than pain.

Physiologic and behavioral signs and symptoms can indicate pain, but lack of these signs does not indicate absence of pain, particularly in chronically or very ill children, in whom these indicators are unreliable. In one study comparing a behavioral pain measure with two self-report measures, many children who reported severe pain showed few behavioral pain indicators.[27] In addition, these signs are not necessarily specific for pain itself and may reflect distress that may or may not be related to pain. Parental and clinician estimates of the child's pain also have limitations, because clinicians and parents frequently underestimate pain.[28,29]

Examples of symptom assessment tools for children of various ages and developmental capacities are demonstrated in Figure 71-2. These tools may be helpful in assessing symptoms and measuring severity before and after interventions. However, they are not all validated specifically for the population of children with cancer.[30] A given tool should be used consistently with a given child. When the assessment reveals the presence of pain, further inquiry regarding the nature of the pain (e.g., the character of the pain and aggravating and alleviating factors) and the meaning that the pain holds for the child and the family is in order.

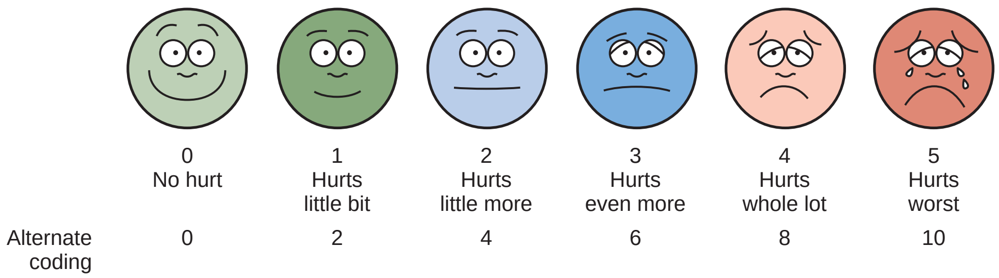
Self-Report Instruments

Many children 3 years of age or older are able self-report their symptoms. Because some young children, FLACC Behavioral Scale: Recommended for Children <3 Years of Age

Categories*	Scoring* 0	1	2
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers; occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to, distractable	Difficulty to console or comfort

A

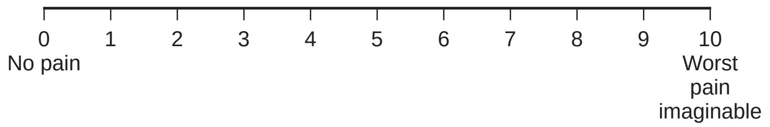
Wong-Baker FACES Pain Rating Scale: Recommended for Children ≥3 Years of Age



Brief word instructions: Point to each face using the words to describe the pain intensity. Ask the child to choose face that best describes own pain and record the appropriate number.

B

Numerical Rating Scale: Recommended for Children ≥8 Years of Age



C

Each of the five categories is scored from 0 to 2, which results in a total score between 0 and 10. **B,** The Wong-Baker FACES Pain Rating Scale, recommended for children 3 years of age and older. Brief word instructions: Point to each face, using the words to describe the pain intensity. Ask the child to choose the face that best describes his or her own pain and record the appropriate number. **C,** The Numerical Pain Rating Scale, recommended for children 8 years and older. *(**A,** From Merkel SI, Voepel-Lewis T, Shayevitz JR, et al: The FLACC: A behavioral scale for scoring postoperative pain in young children.* Pediatr Nurs *23:293–297, 1997;* **B** *and* **C,** *Modified from Hockenberry MJ, Wilson D, Winkelstein ML:* Wong's essentials of pediatric nursing, *ed 7, St. Louis, 2005, Mosby, p. 1259.)*

particularly those who are chronically ill, may be more mature than their chronologic age, the responses even of young children should be heeded. Self-report scales for children include faces scales, color analogue scales, visual analogue scales,[31] the Poker Chip Tool,[32] and numeric rating scales. With the faces scales, such as the Wong-Baker Faces Scale[33] and the Bieri Faces Pain Scale,[34] the child is asked to match how he or she feels with one of the faces. Color analogue scales and faces scales can be used by most children ages 4 years and older. Faces scales differ psychometrically; an example is the use of a smiling face for the "no pain" anchor in the Wong-Baker Faces Scale versus a neutral face for the "no pain anchor" in the Bieri Faces Pain Scale. Although children often report that they like using the Wong-Baker Scale, some researchers regard the use of a neutral face for the "no pain anchor," as in the Bieri Faces Pain Scale, to be psychometrically more specific. With the visual analogue scale, a child selects a point on a line that represents the intensity of his or her pain. These scales have been extensively studied and are appropriate for children 8 years and older.

Numeric rating scales do not require any equipment, are simple to use, and are already used frequently with adults. These scales require numeracy and the ability to think and express oneself in quantitative terms and thus are most appropriate for use in children who are at least 8 years of age.[35] Children younger than 8 years may provide an unreliable numeric response because, although they can count, they have do not have an understanding of the quantitative meaning of numbers.[35] All quantitative scales are based on the concept of counting, which is a universal concept for children who have this developmental capacity. It is therefore possible to develop quantitative tools for pain measurement that are appropriate for children of virtually all cultures.[36]

Behavioral Observation Scales

Behavioral and physiologic cues are particularly useful in preverbal children and in children who are not able to verbalize their symptoms because of cognitive impairment, developmental capacity, or sedation. Such scales may rely on facial expressions,[37] motor or verbal responses, or combinations of behavioral and autonomic responses.[38] Behavioral scales may actually rate distress, including fear and anxiety, rather than specifically assessing pain per se.

When using behavior to assess pain, it is important to partner with parents or other caretakers who are particularly familiar with the child, because knowing the child, having familiarity with children who have the same or similar conditions, and having a thorough grasp of the science of symptom management are all important components of effective pain relief.[39] For example, the Paediatric Pain Profile was created to be a usable document for parents to assess and record their child's pain behavior. It is a well-validated instrument that uses behavioral cues, including changes in facial expression, vocal sounds, posture and movements, sleeping, eating, and mood, to assess pain.[40] The Individualized Numeric Rating Scale is an individualized scale for nonverbal children.[41] This scale is an adaptation of the numeric rating scale; it allows parents or other clinicians who know the child well to identify the child's typical pain behavior and rank that behavior on a standard scale from 0 to 10.

The Face, Legs, Activity, Cry, Consolability (FLACC) tool was originally designed to score postoperative pain in children ages 2 to 7 years[42] but has also been validated for postoperative use in children with cognitive impairment.[43] Use of this instrument may be advantageous because it employs a variety of types of measures such as activity and facial expression. Further work in the area of pain assessment in children with developmental or cognitive impairment is needed because children in these vulnerable populations are less likely to be assessed for pain, in addition to receiving less analgesic medication.[44]

The previously discussed assessment scales largely reduce pain assessment to the measurement of pain intensity. Although such pain assessment is an oversimplification, the scales permit rapid evaluation of pain and rapid institution of interventions aimed at ameliorating pain. Such scales are also key outcome measures in evaluations of pain-relieving interventions. Findings from a recent study, however, highlight the fact that such a simple screening for pain intensity fails to identify many persons who have significant functional interference from pain or pain significant enough to trigger a physician visit.[45] Regardless of the scale used, if clinical pain indicators are unclear, a trial of measures to ameliorate pain may clarify the cause of distress or pain.

Beyond Assessment Instruments

Beyond use of formal assessment tools, key elements in the history include alleviating/exacerbating factors; the quality, location, onset, and severity of pain; and the degree of impact on the child's function and well-being. Understanding the child's previous experiences with pain and strategies that have been used successfully in the past to address pain are also key components of the history and may inform the treatment plan. To this end a multidimensional indicator of pain can help the clinician understand the existence, intensity, and location of pain that a child is experiencing. Use of techniques that employ more than one measure (e.g., self-report, behavioral, and physiologic) permit a more accurate pain assessment.

In addition, it is necessary to understand the holistic nature of pain, rather than pain as merely a physiologic phenomenon. For example, the meaning of the pain, the degree of distress it causes, and the impact of pain and pain treatment on the child's functional capacity and quality of life are crucial elements of the history. Exploration of these issues may elicit exacerbating and potentially modifiable factors related to the pain experience. Finally, it is important to gain a clear understanding of the beliefs that the child and family have about pain, as well as their treatment goals in terms of pain control.

Approach to the Child with Pain

Anticipation and prevention of pain is the most effective treatment approach. Just as children and parents need information regarding their cancer treatment so they know what to expect, informing them in a sensitive manner about the symptoms they may expect and strategies available for reducing their symptoms can reduce anxiety about the unknown. In many cases, without open conversations in which expectations can be addressed, the imagined reality that is substituted is far worse than the true reality. By helping children understand what will happen and how the treatment or procedure will work, their fear and anxiety may be allayed, thereby reducing the symptoms they may actually experience.

When a child reports pain, careful assessment with use of history and physical examination is imperative to generate a complete differential diagnosis. Determination of the underlying cause of pain may inform consideration of which modalities are likely to be most effective in alleviating it. Both pharmacologic and nonpharmacologic (e.g., cognitive, behavioral, physical, and supportive) approaches should be considered, including addressing factors that are likely to affect the child's experience of pain. Once a pain treatment plan is implemented, pain should be regularly reassessed. The goal of pain management should be to achieve the degree of comfort that the child finds satisfactory.

To provide optimal pain control and prevent breakthrough pain, analgesics should in most cases be administered "By the ladder, by the clock, by the appropriate route, by the child" (WHO), and behavioral, physical, and cognitive supports should be provided throughout treatment. Pain of a moderate to severe rating should be treated with analgesics that are administered around the clock, with rescue doses of the same or an alternative analgesic available. Families often find it helpful to understand that preemptive analgesia is far more effective than catch-up analgesia administered for established pain.

Finally, the dosing interval as determined by the pharmacokinetics of the agents considered and the feasibility of their administration by caregivers should also be considered.

WHO Guidelines

The WHO guidelines previously provided a three-step approach to cancer-related pain in children and adults. For mild pain in a child who is not taking any analgesics, an NSAID or acetaminophen was suggested. For moderate pain, a short-acting weak opioid (e.g., codeine) was recommended, and for severe pain, a strong opioid was recommended (e.g., morphine).

The three-step WHO guidelines, which were widely publicized for cancer-related pain, provided an effective approach to pain control for many adults, with published success rates of 69% to 100%.[46-48] However, the three-step ladder consisting of nonopioids, weak opioids, and strong opioids may not be appropriate for some patients with cancer, particularly those with advanced disease. In fact, studies have shown that a two-step ladder in which treatment passes directly from step I (nonopioids) to step III (strong opioids) for mild to moderate pain provides superior pain relief.[49,50] Some medications historically used in step II (e.g., codeine and tramadol) are unlikely to provide better control of moderate pain compared with continuation of acetaminophen and NSAIDs (unless contraindicated) along with titrated doses of a strong opioid. Furthermore, codeine presents safety and efficacy concerns (discussed later), and few data exist to guide the administration of tramadol or other intermediate-potency analgesic agents in children. For these reasons, the most recent WHO guidelines for the management of pain in children with cancer (or other medical illness) are now based on a two-step approach.[51]

The WHO guidelines, which provide an effective, systematic approach to pain that includes strong opioids, have facilitated other WHO initiatives, such as increasing worldwide access to essential medicines for children with painful conditions. The WHO approach, however, may not adequately emphasize a multidisciplinary approach from the start, and thus opportunities to use adjuvant medications (e.g., steroids and local anesthetics) and cognitive or behavioral interventions to reduce pain and pathologic responses to pain may be missed.

Analgesic Medications and Interventions

Nonopioid Analgesics

Nonopioid analgesics are appropriate for mild pain in a child who is not already receiving analgesics. Nonopioid analgesics include acetaminophen, NSAIDs, salicylates, and selective cyclooxygenase (COX-2) inhibitors.

Nonopioid analgesics are frequently used as monotherapy for mild pain and are used together with opioids for more severe pain. Unlike opioids, they do not cause sedation, tolerance, and respiratory depression. When given as an adjuvant to opioids, they enhance analgesia.[52,53] To this end they may be opioid-sparing (i.e., decreasing the amount of opioid required for adequate analgesia),[54,55] thereby also limiting opioid-associated adverse effects. A recent randomized double-blind study of infants who underwent noncardiac surgery demonstrated that children randomly assigned to receive intermittent intravenous (IV) paracetamol with morphine as needed for rescue required only about one third as much rescue morphine as children randomly assigned to receive an IV placebo.[56] Combinations of nonopioids and opioids are available, although dosing of such a combination is often limited by the maximum dose of the nonopioid.

Salicylates and NSAIDs

Salicylates and NSAIDs nonspecifically inhibit cyclooxygenase enzymes, thereby blocking production of a variety of prostaglandins that mediate pain, inflammation, fever, and platelet function, protect gastric mucosa, and maintain a physiologic distribution of blood flow in the liver and kidneys. The permanent effects of aspirin on platelet function via permanent acetylation of cyclooxygenase are of particular concern in patients who have thrombocytopenia because the antiplatelet effect lasts even after the drug has been metabolized. Choline magnesium salicylate (Trilisate) is a salicylate that provides many of the same benefits as those provided by other salicylates or NSAIDs without known antiplatelet activity. Salicylates, however, have been associated with Reye syndrome in children younger than 2 years.

No particular NSAID or route of administration has been found to be superior over another. Even ketorolac, the only parenteral NSAID widely used in the United States, is no more effective than orally administered NSAIDs, especially if doses are compared in an equitoxic range. A single NSAID dose is roughly equivalent to 5 to 10 mg of intramuscular morphine in adults and has fewer adverse effects.[57] NSAIDs are commonly regarded as having a ceiling effect with no added benefit at supramaximal doses, although the doses commonly recommended (based on safety concerns) remain well below the ceiling in most cases. NSAIDs can cause nephropathy, gastritis, and bleeding from reversible platelet dysfunction, a characteristic that may limit their use in patients with cancer who are thrombocytopenic. COX-2 inhibitors (e.g., celecoxib) selectively block production of prostaglandins that mediate inflammation and pain without impairing platelet function and with fewer effects on gastric mucosal integrity compared with traditional NSAIDs, particularly with short-term use.[58,59] Concerns have been raised regarding effects of COX-2 inhibitors on the risk of cardiovascular events in adults. Evidence does not currently indicate that these concerns extend to children with neoplasms, including the small subgroup of children with tumors or vascular anomalies who have an increased risk of thrombotic events.

Acetaminophen

Acetaminophen is a nonopioid analgesic that reduces pain and fever. It may act in part by inhibiting prostaglandin synthesis in the CNS. Unlike salicylates and NSAIDs, which inhibit peripheral cyclooxygenases, it does not have peripheral antiinflammatory properties. Acetaminophen is available in a variety of oral formulations, as an IV formulation (approved in the United States for children ≥2 years), and as a rectal suppository, although rectal administration should be avoided in neutropenic patients. When not contraindicated, rectal administration is helpful for children unwilling or unable to take oral medications, although its absorption is slow and variable, peaking at 70 minutes.[60] Because rectal absorption is less efficient, single doses of 30 to 40 mg/kg can be administered.[60] Subsequent doses should be smaller (20 mg/kg), and the interval between doses should be increased to 6 to 8 hours.[60,61] Dosing of oral or IV acetaminophen is limited to 75 mg/kg/day or a maximum of 4 g/day (whichever is smaller) because of the risk of hepatic toxicity.

Opioid Analgesics

General Considerations. Guidelines for initial opioid dosages are presented in Table 71-1 and are discussed in

TABLE 71-1 Guidelines for Initial Dosages for Opioid Analgesics[*]

	EQUIANALGESIC DOSES		USUAL STARTING IV OR SUBCUTANEOUS DOSES AND INTERVALS			USUAL STARTING ORAL DOSES AND INTERVALS	
Drug	**Parenteral**	**Oral**	**Child <50 kg**	**Child ≥50 kg**	**Ratio of Parenteral to Oral Dose**	**Child <50 kg**	**Child ≥50 kg**
Morphine	10 mg	30 mg (long term) 60 mg (single dose)	Bolus: 0.1 mg/kg every 2-4 h Infusion: 0.03 mg/kg/h	Bolus: 5-8 mg every 2-4 h Infusion: 1.5 mg/h	1:3 (long term) 1:6 (single dose)	Immediate release: 0.3 mg/kg every 3-4 h Sustained release: 20-35 kg: 10-15 mg every 8-12 h 35-50 kg: 15-30 mg every 8-12 h	Immediate release: 5-20 mg every 3-4 h Sustained release: 30-45 mg every 8-12 h
Oxycodone	NA	15-20 mg	NA	NA	NA	0.1-0.2 mg/kg every 3-4 h	5-10 mg every 3-4 h
Methadone[†]	10 mg	10-20 mg	0.1 mg/kg every 4-8 h	5-8 mg every 4-8 h	1:2	0.1-0.2 mg/kg every 4-8 h	5-10 mg every 4-8 h
Fentanyl	100 µg (0.1 mg)	NA	Bolus: 0.5-1.0 µg/kg every 1-2 h Infusion: 0.5-2.0 mg/kg/h	Bolus: 25-50 µg every 1-2 h Infusion: 25-100 µg/h	NA	NA	NA
Hydromorphone	1.5-2 mg	6-8 mg	Bolus: 0.02 mg/kg every 2-4 h Infusion: 0.006 mg/kg/h	Bolus: 1 mg every 2-4 h Infusion: 0.03 mg/h	1:4	0.04-0.08 mg/kg every 3-4 h	2-4 mg every 3-4 h
Meperidine (pethidine)[‡]	75-100 mg	300 mg	Bolus: 0.8-1.0 mg/kg every 2-3 h	Bolus: 50-75 mg every 2-3 h	1:4	2-3 mg/kg every 3-4 h	100-150 mg every 3-4 h

Modified from Berde CB, Sethna N: Analgesics for the treatment of pain in children. N Engl J Med *347:1094–1103, 2002. All doses are approximate and should be adjusted according to clinical circumstances. Recommendations are modified from previous summary tables, including those of a consensus statement from the World Health Organization and the International Association for the Study of Pain.*

IV, Intravenous; *NA,* not applicable.

[*] Doses are for patients older than 6 months of age. In infants younger than 6 months, initial per-kilogram doses should begin at roughly 25% of the per-kilogram doses recommended here. Higher doses are often required for patients receiving mechanical ventilation.

[†] Use of methadone requires additional vigilance because it can accumulate and produce delayed sedation. If sedation occurs, doses should be withheld until sedation resolves. Thereafter, doses should be substantially reduced; the interval between doses should be extended to 8 to 12 hours, or both.

[‡] Use of meperidine, especially long-term use, should generally be avoided if other opioids are available, because its metabolites can cause seizures.

greater detail in this section. Ultimately, the correct dose of opioid is the dose that provides the desired analgesia with acceptable adverse effects. In general, intolerable adverse effects are usually the dose-limiting factor, as opposed to opioids having a ceiling effect. This situation should be explained to parents, as well the fact that, with rare exceptions, *children with cancer who receive opioids for pain control do not become addicted to opioids*. Addiction is an aberrant psychiatric condition in which the person exhibits maladapted, drug-seeking behavior. True addiction is comparatively rare in patients with cancer-related pain. Children who exhibit exaggerated pain behaviors (e.g., demanding pain medication and engaging in manipulative behaviors) are far more likely to be demonstrating pseudoaddiction, in which case their behavior is a reflection of poorly controlled pain.

Addiction should be distinguished from dependence, that is, a physiologic response to opioids in which abrupt removal leads the patient to experience symptoms of withdrawal. It may be helpful to draw a parallel to blood pressure medication, the abrupt cessation of which causes an undesired rebound hypertensive effect because the body has adjusted to the presence of the antihypertensive drug. Addiction should also be distinguished from tolerance, which is another physiologic response of the body to the presence of opioids that requires increasing doses to achieve the same analgesic effect. *The need to adjust dosing to account for tolerance is not an indication of addiction*. Other processes that can resemble tolerance, including opioid-induced hyperalgesia, are discussed later in this chapter.

Opioids do not need to be saved for cases of extreme pain, because increasing pain can often be managed by increasing the opioid dose. In addition, when escalating doses provide marginal benefit, rotating to an alternative opioid may provide better analgesia. It may be helpful to explain to parents that good pain control from the start may improve pain control overall and actually minimize the amount of opioid that is ultimately needed because when good pain control is achieved, the need to use large doses required to catch up to uncontrolled pain can be avoided.

Some children who have cancer, particularly advanced cancer, require extremely high doses of opioids. For example, in a sample of children with advanced cancer, Collins and colleagues[62] found that in some patients the opioid infusions ranged more than 100-fold from 3.8 to 518 mg per hour of morphine equivalent.

Some studies conducted in vitro and in animal models have demonstrated that opioids may promote cancer cell growth by affecting processes such as tumor cell proliferation and migration. For example, opioids at physiologically relevant concentrations promote tumor angiogenesis.[63,64] In addition, the opioid receptor antagonist naloxone and the COX-2 inhibitor celecoxib inhibit angiogenesis, tumor growth, and metastasis in rodents.[64,65] However, other studies demonstrate growth-inhibiting effects of opioids and have been reviewed elsewhere.[66] No evidence to date demonstrates opioid-associated promotion of tumor growth in humans. These preliminary findings should not, by themselves, lead to the conclusion that use of opioids to relieve cancer-related pain should be avoided. The data accumulated to date regarding the potential risks of opioids and the benefits of adequate analgesia are insufficient to recommend limiting opioid use for analgesia.

Developmental Pharmacology. Elements of renal clearance such as glomerular filtration and tubular secretion increase in the first few weeks of life, such that renal clearance commensurate with adult clearance is achieved by 8 months. When compared with children and adults, neonates and infants have reduced hepatic clearance as a result of hepatic enzyme immaturity. In addition, children 2 to 6 years of age have higher clearance than do adults because of a larger liver mass to body weight ratio.[67] As a result, drugs may need to be administered more frequently in children than they are in adults. Other age-related differences, such as changes in body composition and plasma concentrations of drug-binding proteins, can also influence pharmacokinetics.

Choice of Opioid. The usual starting opioid is morphine because of its low cost, wide availability, multiple routes of administration, and familiarity to clinicians. Because of its long history of use in children, it should be considered the first-line opioid in this population unless specific reasons exist to consider alternatives. Alternative opioids including oxycodone, hydromorphone, and semisynthetic and synthetic compounds such as fentanyl and methadone can be used in children. Use of alternative opioids may be predicated on availability, route of administration, presence of organ impairment, and the patient's prior experience with particular opioids.

Renal Failure. Metabolites of morphine, oxycodone, and hydromorphone (discussed later) may accumulate during renal failure. Some metabolites have analgesic activity, which may lead to delayed opioid toxicity (opioid neurotoxicity will be discussed later). For this reason, dosing intervals may need to be increased in patients with renal dysfunction. The pharmacokinetics of alternative opioids such as fentanyl and methadone are not changed with renal impairment, making these opioids better choices in this setting.

Hepatic Failure. Because glucuronidation is relatively well preserved in persons with liver failure, opioids metabolized by glucuronidation (i.e., morphine, hydromorphone, and buprenorphine) are generally better choices than those metabolized by oxidation via liver cytochromes (e.g., oxycodone, fentanyl, and methadone) in this setting.[68] However, because of shunting in persons with liver cirrhosis, the bioavailability of glucuronidated opioids may be increased. For this reason, initial opioid doses should be lower in persons with hepatic impairment.

Weak Opioids. Tramadol is an atypical analgesic with some direct noradrenergic and serotonergic agonist action and with an active metabolite that is a weak opioid. Tramadol has numerous drug-to-drug interactions that should be considered. For example, it can produce seizures by itself, but this risk is greatly increased when tramadol is administered in combination with several classes of antidepressants. It is available in oral immediate and extended-release preparations and in combination formulations with acetaminophen.

Although codeine has historically been recommended as a weak opioid for mild to moderate pain, it has several limitations. The variable expression of the CYP2D6 enzyme that biotransforms codeine leads to unpredictable levels of the active metabolite, morphine. In the fetus, CYP2D6 activity is absent, and in children younger than 5 years, CYP2D6 activity is less than 25% that of adult activity.[51] Furthermore, certain genotypes are associated with reduced enzyme activity, regardless of age. In a study of 96 children randomly assigned to receive either morphine and diclofenac or codeine and diclofenac after an adenotonsillectomy, it was found that 47% of children had genotypes associated with reduced enzyme activity and that neither morphine nor its metabolites were detected in 36% of children with reduced CYP2D6 activity genotypes who received codeine, although the study did not account for other factors influencing catalytic rate, such as gene copy number.[69] Such "poor metabolizers" of codeine were more likely to have uncontrolled pain and to require rescue medication.

On the other hand, persons who are "ultrarapid metabolizers" may possess multiple copies of the *CYP2D6* gene responsible for codeine metabolism or have genotypes associated with rapid metabolism and may therefore be at risk for adverse effects such as respiratory depression from rapid generation of morphine from codeine. Several pediatric deaths from codeine administered after a tonsillectomy and/or an adenoidectomy have resulted from such ultrarapid metabolism. It is for this reason that the U.S. Food and Drug Administration (FDA) has issued a "boxed warning" and deemed codeine contraindicated in this setting.

In a variety of painful conditions in children, provision of codeine provides no benefit greater than that of NSAIDs. When codeine, ibuprofen, and acetaminophen monotherapy were compared in children with musculoskeletal trauma who presented to an emergency department, ibuprofen provided superior analgesia.[70] In the posttonsillectomy setting, codeine in combination with acetaminophen caused more nausea with no difference in pain or postoperative bleeding.[71] A meta-analysis also found that weak opioids (i.e., codeine) in combination with NSAIDs fail to provide superior analgesia to that provided by NSAIDs alone[57] but do have significantly more adverse effects. Based on these findings, in our view, very few instances exist in which codeine is a preferred choice among opioids.

Some opioids exhibit partial mu receptor agonist activity (e.g., buprenorphine), kappa agonist activity (e.g., nalbuphine), or mixed agonist activity (e.g., butorphanol and pentazocine). Although these opioids have predominantly agonist activity, some have significant antagonist activity as well, and thus they may reduce the effect of pure mu agonists given concurrently. In general they do not provide superior analgesia, although they may have fewer gastrointestinal (GI) or respiratory adverse effects and may be considered for individual patients who have limiting adverse effects with other opioids. Currently the greatest use of buprenorphine in the United States is for substance abuse treatment. It has been used by multiple routes for treatment of cancer-related pain in children, particularly in countries with greater impediments to the prescribing of morphine, methadone, or other opioids. Authors of a recent small prospective case series reported reasonable effectiveness and tolerability of transdermal buprenorphine for children with cancer.[72]

Strong Opioids. Meperidine is a strong opioid that should be avoided in most cases because of its adverse effect profile and lack of superiority to the strong opioids described in the next sections. For example, repeated doses of meperidine lead to accumulation of its metabolite, normeperidine, which in turn causes neuroexcitatory symptoms including agitation, tremors, myoclonus, and seizures.[73] In a double-blind trial comparing morphine with meperidine administered via patient-controlled analgesia (PCA), it was found that morphine resulted in better analgesia and had no more adverse effects than did meperidine.[74] In low doses, meperidine reduces postoperative shivering or rigors associated with amphotericin infusion.

Morphine. Morphine is the most frequently prescribed opioid in children and is the best studied opioid in this population. It offers flexibility in terms of routes of administration. It is also available in a controlled-release formulation, and multiple randomized controlled trials have shown that this formulation can effectively control cancer-related pain when administered every 12 hours.[75] Morphine is extensively metabolized by glucuronidation in the liver to morphine 3-glucuronide (M3G) and morphine 6-glucuronide (M6G). M3G does not bind mu receptors and has no analgesic activity but may contribute to some of the neuroexcitatory adverse effects of morphine.[76] On the other hand,M6G does bind mu receptors and is a potent analgesic.[77,78]

Oxycodone. Oxycodone is a semisynthetic derivative of morphine. Although it is frequently categorized as a weak opioid appropriate for mild to moderate pain (and is frequently administered in combination with acetaminophen), this categorization is a reflection of its use at low doses. In fact, a meta-analysis showed that oxycodone is as efficacious an analgesic as morphine or hydromorphone.[79] This meta-analysis also showed no difference between oxycodone and morphine in terms of adverse effects such as dry mouth, sedation, or nausea.[79] Oxycodone itself has no ceiling effect or dose limit, although dosing may be limited when it is administered in combination with nonopioid agents such as acetaminophen. Although it is available in parenteral formulations in other countries, in the United States it is only available in an oral formulation. The oral formulation is available in an extended-release preparation.

Oxycodone is predominantly metabolized by CYP3A4 to inactive products. A secondary pathway involving CYP2D6 may lead to generation of the active opioid oxymorphone in patients with ultrarapid metabolizing variants. Although cases of apnea and death associated with excessive conversion from oxycodone to oxymorphone have been published, the prevailing impression is that pharmacogenomic variation overall leads to less variance in effect for oxycodone compared with codeine. Oxycodone pharmacokinetics have been studied in children,[80] but there is a need for additional pediatric pharmacokinetic/pharmacodynamic studies that include oxymorphone assay, pharmacodynamic end points, and contemporary genotyping.

Hydromorphone. Hydromorphone may be administered orally, intravenously, or subcutaneously. Although it was previously thought that hydromorphone has less neurotoxicity, hydromorphone metabolites have recently been shown to convey neuroexcitatory adverse effects. One advantage of hydromorphone compared with morphine is that its higher potency allows for smaller subcutaneous volumes to be delivered when this route of administration is utilized.

Fentanyl. Fentanyl may be given intravenously with rapid onset of action and short duration of action (20 to 30 minutes). For this reason fentanyl is frequently used as an analgesic for brief, painful procedures. Rapid administration of fentanyl may cause chest wall rigidity that requires reversal with naloxone or even neuromuscular blockade and positive pressure ventilation.[81] In occasional patients, fentanyl may be better tolerated than other opioids, in part because it is associated with less histamine release[82] and creates no metabolites that may produce neurotoxicity.

Fentanyl transdermal patches last 72 hours and are a convenient parenteral mode of drug delivery that is preferred by many adults.[83,84] These patches have also been used successfully in children who have chronic pain.[85] Although wide within-individual variability in fentanyl absorption exists, intraindividual absorption is reported to be stable.[86,87] In addition, hyperhidrosis, hypertrichosis, and the localization of patches on the skin do not appear to affect fentanyl absorption.[86] Because the onset of action is at least 12 hours, and because some fentanyl remains in the system for 72 hours after patch removal, transdermal fentanyl lacks flexibility for close titration for rapidly changing pain severity. The smallest patch size (12 μg/h) may be too large a dose for some children. For children as young as 2 years who had previously taken opioids and had developed some degree of tolerance, transdermal fentanyl was found to be a safe and well-tolerated alternative to oral opioid treatment.[85] The reservoir design of the patch prevents the patch from being cut to adjust the dose delivered. Transdermal fentanyl should be avoided in patients who have not previously taken opioids because it may result in respiratory depression.

In addition to rapid onset of action and transdermal application, fentanyl provides several other benefits. When renal function is impaired, fentanyl does not accumulate to the same extent as morphine.[88] Some studies have demonstrated that transdermal fentanyl appears to cause less constipation than does oral morphine, but it is unknown whether this observation is related to the route or the drug.[89-91]

In adults or children already receiving 60 mg/day of morphine, oral transmucosal fentanyl citrate (OTFC, or Actiq) provides extremely rapid control of incident pain, with an onset of action of 5 to 10 minutes. This rapid onset of action is due to its lipophilic nature, as well as because this route bypasses first-pass hepatic metabolism. Because of the rapidity of its onset of action, OTFC has been used to provide analgesia for brief, painful procedures without the requirement for IV access.[92] OTFC is also quite useful for patients who have breakthrough pain. In a double-blind, double-dummy, randomized, crossover study of adult patients with cancer who had incident (breakthrough) pain, it was found that OTFC reduced pain intensity more effectively than did immediate-release oral morphine, and OTFC was favored over immediate-release morphine sulfate by more patients after the study.[93] No conversion ratio is available for OTFC, and careful titration is needed to determine the correct dose. No correlation exists between the effective OTFC dose and the around-the-clock dose of an opioid.[94] For this reason the lowest strength (200 μg) should be tried first. If inadequate pain relief is achieved in 20 minutes, this dose may be repeated.

The fentanyl buccal tablet is another preparation of fentanyl that is rapidly absorbed through effervescent action through the oral mucosa. Patients should be taking at least 60 mg/day of oral morphine so they have opioid tolerance to safely receive a fixed dose of fentanyl with such rapid onset of action through the oral mucosa. The need for this degree of tolerance is highlighted by recent experiences with buccal/sublingual fentanyl tablets, which, when (inappropriately) administered to opioid-naive patients, may result in life-threatening respiratory depression.

Methadone. Methadone may be given orally (it is available as a tablet or liquid) or intravenously. One advantage to methadone in the pediatric population is that it is the only long-acting opioid widely available in liquid formulation. In addition, it is relatively inexpensive to manufacture, costing 90% less than extended-release morphine.[95] Methadone also exhibits unique receptor-binding properties in that the l-isomer binds mu opioid receptors and the d-isomer binds the N-methyl-d-aspartate (NMDA) receptor. Because the NMDA receptor is involved in opioid tolerance, opioid hyperalgesia, and neuropathic pain, it may be a useful opioid in these clinical situations, which are discussed later. For these reasons, administration of methadone for analgesic purposes has become more popular in recent years.

The variable pharmacologic half-life of methadone, which ranges from 12 to 150 hours, may result in delayed toxicity (e.g., sedation and hypoventilation) that can occur many days after initiation of the drug.[96] The analgesic half-life of methadone is commonly cited as 4 to 6 hours,[97] although some patients can require minimal rescue analgesia with dosing at 8- or 12-hour intervals. In addition, equianalgesic dose conversion from other opioids is variable and depends in part on the dose of the previous opioid. Its potency relative to morphine is highly dependent on the previous morphine dose.[98,99] A very convenient website, www.globalrph.com/narcoticconv.htm, can be used to assist in dose conversions. It should be emphasized that even with these calculations, enormous individual variability exists, and close follow-up is required to avoid delayed oversedation.

Methadone is metabolized through several cytochromes and therefore interacts with a variety of other medications. Individual variation in cytochrome expression may account in part for significant blood concentration variability in patients.[100,101] Methadone, in conjunction with other medications, may prolong the QTc interval.[102] It is unclear whether this phenomenon explains the otherwise unexplained increased incidence of sudden cardiac arrest in adults receiving methadone therapy.[103] Until the potential for methadone to pose cardiotoxicity is better understood, it should be used cautiously in children who have underlying cardiac conditions or those at risk for prolonged QTc. Although methadone has several advantages, it also has some unique features that require familiarity with this agent for safe and effective use. The majority of pediatric oncologists rarely, if ever, prescribe methadone.[104] Lack of familiarity with methadone pharmacodynamics, effectiveness, and dosing equivalence are the most common reasons cited for prescribing other opioids rather than methadone.

Oxymorphone. Oxymorphone is the active metabolite of oxycodone and is available as a rectal suppository. An extended-release oral formulation has also recently been approved.

Opioid Starting Doses. For the opioid-naive patient, recommended starting doses are listed in Table 71-1. For infants younger than 6 months, the starting dose should be roughly one fourth the weight-scaled dose suggested in the table and titrated to effect. Opioids should be administered with caution in patients who have disordered control of respiration, altered mental status, or altered drug metabolism. This is not to say, however, that opioids should be withheld from these patients. In fact, opioids can be safely delivered and adequate analgesia achieved with careful titration to effect.

Routes and Methods of Administration. Medication should be given by the simplest, most effective, and least distressing route. Other considerations that should guide the choice of route include the severity and type of pain, the ability of the child to tolerate a given route due to developmental or personal factors, and the ability of the caregivers to administer medication via certain routes.

Oral. When possible, the oral route of administration should be attempted first. In general, the time for opioids to reach peak effect is about 60 minutes with the oral route. Most extended-release preparations are available in tablets or capsules. For children who cannot swallow tablets or capsules but who would benefit from an extended-action preparation or agent, liquid methadone can be used. If the child has a gastrostomy tube, ultra–extended-release morphine (given every 24 hours) may be suspended *(but not crushed)* and administered via a gastrostomy tube. Ultra–extended-release morphine allows once-daily oral dosing, but unintended chewing or crushing may lead to overdose from immediate release of the morphine.[105,106] Opening the capsules and sprinkling the drug onto applesauce may be an appropriate administration technique for adults[105] but should be avoided in young children. Ultra–extended-release morphine may be considered for adolescents, but in younger children who may be at risk for accidentally chewing the capsules, these preparations should generally be avoided.

For intermittent dosing, oral opioids prepared as concentrated drops may provide analgesia without the requirement of swallowing larger volumes of liquid. Concentrated morphine may be helpful for children who are unable to reliably take oral opioids because of their neurodevelopmental capacity or nausea and vomiting.

Rectal. Suppositories containing hydromorphone and morphine may be administered rectally. In addition, controlled-release morphine tablets may be given rectally.[107] Although the published potency of rectal opioids approximates that of oral opioids,[108] the pharmacokinetic properties of morphine, that is, first-pass metabolism to the active metabolite M6G by the portal circulation, should be considered when considering rectal administration. For example, Wilkinson and colleagues[107] determined that the area under concentration-time curves for morphine metabolites were approximately twice those achieved after rectal administration. The maximal concentration of morphine and its metabolites was lower and the time to achieve peak levels was longer for rectal administration. In this study, the variation in morphine kinetics did not correspond with altered pain ratings.[107] Although it is reasonable to start with 1 : 1 (oral to rectal) equianalgesic dosing of morphine, adjustments in the dose or dosing interval should be anticipated.

Transdermal. Fentanyl and buprenorphine are the only opioids manufactured in transdermal formulations. The transdermal route for delivery of fentanyl or buprenorphine provides some advantages. Other opioids such as morphine may be compounded as transdermal formulations, but absorption of these other opioids via this route is unreliable, and alternative means of opioid administration are almost invariably available.

Intravenous. Use of the IV route, when appropriate, may provide rapid and reliable administration. In general, the time for morphine to reach its peak effect is about 15 minutes via this route. The IV route is frequently used for patients who have severe pain or for children who are unable to take oral medications, such as children who are in the final stages of life.[14]

Subcutaneous. All IV opioids may be administered subcutaneously, although methadone may cause local irritation if infused continuously.[109] Delivery of opioids by this route dose adds approximately 30 minutes to the time of peak effect obtained by IV administration. This route is simple to use and requires only a portable syringe driver to administer the medication through a butterfly needle. In addition, it confers consistent delivery and easy titration without the requirement for IV access. Needles are changed every week or more often if skin irritation occurs, and this task can often be performed by a family member. In our experience, children can absorb 2 mL per hour, whereas adults can absorb 3 to 5 mL per hour. Higher doses of opioids may exceed these volume limits. In such cases, switching to a more potent opioid, such as hydromorphone, may be necessary.

Patient-Controlled Analgesia. PCA can provide a continuous IV or subcutaneous infusion of opioid to provide basal control of pain, as well as a bolus, which provides relief from breakthrough pain. The PCA delivery system allows patients to manage their pain themselves, and no lag time exists between the request and delivery of a bolus dose for uncontrolled pain, increasing their sense of control over their pain. In one study comparing continuous infusion morphine with PCA, it was found that patients who used PCA required less total opioid while receiving equivalent control of the pain of mucositis associated with bone marrow transplantation.[110]

Because opioid-induced sedation generally occurs before respiratory depression, it is rare for a patient to administer boluses to himself or herself to the point of respiratory depression. PCA delivery has been used in the pediatric population with safety and efficacy. PCA does not increase the incidence of opioid-related complications, including sedation.[111] Clinical protocols for calculating the PCA commencement opioid dose and subsequent opioid-dose escalation can facilitate the safe and efficacious implementation of PCA.[112] Thorough assessment of PCA use includes the total daily dose, ratio between continuous and bolus opioid, amount of baseline and breakthrough pain, and response to the bolus dose. A common recommendation is to adjust the continuous (basal) rate to supply roughly two thirds of the patient's daily opioid requirement. Although this starting point is reasonable for most oncology patients with persistent disease-related pain, individual circumstances exist in which the parameters should be modified. For example, in the setting of brief, severe, episodic pain, it may be reasonable to use a lower basal rate and give more generous boluses. In postoperative care, considerable variation exists in the use of basal infusions. Our practice is to use them for operations expected to result in more severe pain and/or in patients who are likely to underdose themselves. Conversely, we tend to avoid basal infusions or use very low basal rates for patients who have less painful surgery, for patients who have received other nonopioid methods of analgesia (e.g., peripheral nerve blocks or plexus blocks), or for patients who have factors that increase respiratory risks.

PCA has been used successfully in children as young as 4 years of age.[113] PCA may also be administered by surrogates, commonly as nurse-controlled analgesia or parent-controlled analgesia, or collectively as PCA-by-proxy. In theory the safety of PCA is maximized when the patient self-administers the medication, because when the patient falls asleep, he or she stops pushing the button. Because the proxy assesses the child's pain and provides the bolus dose, the safety feature inherent in a PCA to prevent respiratory depression is overridden, but when it is used appropriately it is associated with only rare respiratory or neurologic complications.[114] Overall, the safety of nurse-controlled analgesia is well established and is widely used for both opioid-tolerant and opioid-naive infants and children. Greater controversy persists with parent-controlled PCA, although experience with this arrangement is mounting.[115] Our general practice is to greatly limit its use for routine care of opioid-naive postoperative infants and children but to use it widely for opioid-tolerant infants and children in palliative care, especially at home. Guidelines to increase the safety of PCA by proxy have been proposed.

Intrathecal. Opioids may be administered intrathecally and are considered later in the "Invasive Approaches to Pain Management" section.

Regardless of the route utilized, if the patient has continuous pain, a regimen providing continuous pain control should be implemented. To establish a patient's true analgesic needs, short-acting opioids, which can be easily titrated, may be administered for the first 24 to 48 hours. Based on the amount of opioid required during the initial interval, a longer acting opioid may then be substituted, with provision of an as-needed short-acting opioid available for incident or breakthrough pain.

Whatever the regimen, ensuring proper follow-up assessment is critical to ensure appropriate analgesia and to evaluate for potential opioid-associated adverse effects. Because constipation is a predicted and preventable adverse effect of opioids, a bowel regimen to prevent this adverse effect should always be instituted and adjusted as necessary whenever opioids are started or escalated.

Breakthrough Pain. Breakthrough pain is a transitory exacerbation of pain that occurs when pain is otherwise relatively controlled or stable at baseline. Patients with chronic cancer-related pain and superimposed breakthrough pain have worse overall pain, more impaired functioning, and higher psychological distress than do patients with chronic cancer-related pain alone.[116] Breakthrough pain may occur as a result of incident pain (i.e., pain due to a stimulus, such as movement or coughing) or end-of-dose failure, or it may be spontaneous in nature (such as lancinating pain attacks in persons with postherpetic neuralgia).

In a prospective study of pediatric inpatients with cancer it was found that 57% experienced one or more episodes of breakthrough pain during the preceding 24 hours, with each episode lasting seconds to minutes and most commonly characterized by the children as "sharp" and "shooting."[117]

Breakthrough pain may be challenging in that its onset may be unpredictable and rapid, and it may be more severe than pain typically experienced at baseline. For these reasons, use of a pain diary may be particularly important in detecting patterns and factors associated with breakthrough pain. If end-of-dose breakthrough pain occurs, the total daily around-the-clock dose may be increased by 25%, although this increase may lead to intolerable adverse effects. Alternatively, the dosing interval may be shortened.

Breakthrough pain should be approached as other types of pain are approached, with (1) consideration of the underlying triggers and interventions aimed at the underlying problem, (2) optimization of the scheduled analgesic regimen, and (3) use of adequate analgesics for episodic pain, that is, rescue medication. The rescue dose to treat such breakthrough pain should be the equivalent to the dose used every 4 hours, or 5% to 10% of the total daily opioid dose. For predictable incident pain, a short-acting opioid given just prior to the activity may be helpful. When the breakthrough pain has neuropathic features, consideration should be given to adjunctive use of analgesics with specificity for these types of pain, that is, anticonvulsants or antidepressants, as will be discussed later.

OTFC may safely provide very rapid pain relief in patients receiving the equivalent of 60 mg/day of oral morphine, as was previously discussed. It may be especially useful when breakthrough pain is unpredictable and short-lived. Other hydrophilic agents such as morphine are often administered sublingually for breakthrough pain but have a longer onset of action. A recent small study indicates that the rapid onset of action of methadone may make it a useful agent for treatment of breakthrough pain.[118]

Dose Escalation. When a patient who is already receiving oral or IV opioids has severe pain that persists despite a dose of breakthrough opioid medication, the dose should be increased by 50% to 100% and repeated. Once adequate analgesia is reached, the total amount given over 4 hours to determine the “effective dose” for every 4 hours should be calculated.[8] If more than two rescue doses are used in a 24-hour period, the total standing dose should be increased.

For patients receiving continuous IV opioids, a rescue dose for breakthrough pain should be provided that consists of 50% to 200% of the hourly infusion every 15 minutes as needed. For the sake of simplicity, use of multiple different short-acting opioids is discouraged.

Opioid Tolerance. The response to acquired tolerance to an opioid is usually to increase the opioid dose. When this approach is not feasible because of opioid adverse effects such as neuroexcitability, rotating to a different opioid may be an option. Because the NMDA receptor plays a role in opioid tolerance, methadone, with its attendant NMDA antagonist properties, may control pain that is otherwise refractory to opioids.[119] The addition of adjuvant NMDA receptor antagonists such as ketamine may also reverse opioid tolerance. In animals, as well as in some patients, chronic administration of opioids can generate a condition of generalized hyperalgesia, meaning that new painful stimuli produce a greater intensity of pain than would have occurred with the same stimulus for that subject in an opioid-naive state. Opioid-induced hyperalgesia is discussed in greater detail later.

Opioid Rotation. Opioid rotation, or switching, may also be indicated as a result of intolerable adverse effects or route of administration. Equianalgesic tables are useful for conversion from one opioid to another and are widely available. Although no evidence exists to demonstrate the superiority of one opioid over another in such a switch, the strategy of changing opioids may be successful in alleviating dose-limiting adverse effects or opioid tolerance in children. For example, Drake and colleagues[120] found that opioid rotation resolved adverse effects in 90% of children without loss of analgesia or the need to increase morphine equivalents. In fact, because of the phenomenon of incomplete tolerance, the equianalgesic dose of the second opioid should be decreased by 20% when a patient is transitioned from one opioid to another. The phenomenon of incomplete tolerance is particularly pronounced when converting to methadone,[98,99] likely because of the ability of the d-isomer of methadone to act as an NMDA receptor antagonist.[121]

Opioid Withdrawal and Opioid Tapering. Opioid withdrawal is a physiologic response. Sudden discontinuation of opioids in a patient who has been taking long-standing opioids may prompt a withdrawal syndrome characterized by irritability, restlessness, dysphoria, anxiety, muscle aches, sweating, piloerection, diarrhea, nausea, vomiting, yawning, and sneezing. Withdrawal may be prevented by tapering opioids. Opioid doses may be safely cut in half without precipitating withdrawal. Continued tapering may be achieved by halving the dose every 3 days. An alternative strategy is to reduce the total daily dose by 10% per day. Maintaining the rescue dose at its original dose during the tapering process allows for effective treatment of breakthrough pain that may occur as the dose is tapered.

Opioid Adverse Effects. Nonrespiratory adverse effects from opioids include constipation, nausea, pruritus, somnolence/sedation, and, particularly at high doses, neurotoxicity. A prospective study of pediatric oncology patients found that in children receiving morphine, postoperatively, 38% had vomiting, 32% had nausea, and 24% had constipation.[122] The high incidence of nausea and vomiting in this population is likely confounded by postoperative nausea and vomiting.

Opioid-associated sedation typically self-resolves within a few days of the institution of opioids. In some cases the sedation observed when instituting opioids is not an adverse effect of opioids per se but rather a result of an exhausted patient finally able to sleep once pain is controlled. Nausea experienced by some patients upon starting opioids similarly self-resolves within a few days and is often relieved with use of an antiemetic. Switching to a different opioid due to nausea within the first 3 days of opioid therapy may be premature. Opioid-associated urinary retention is an uncomfortable symptom that may respond to a switch to an alternative opioid. Anecdotally, urinary retention in some patients may respond to selective alpha-1A antagonists such as tamsulosin, which are commonly prescribed for adults with lower urinary tract outflow obstruction. Urinary retention, frequency, or urgency should prompt a focused consideration of a range of oncologic and neurologic causes, as well as effects of other medications in addition to opioids, such as anticholinergics and antihistamines. Management of opioid-associated sedation/fatigue, constipation, pruritus, and nausea are further discussed in the sections of this chapter dedicated to these specific symptoms.

If adverse effects persist despite appropriate interventions, rotation to a different opioid may be helpful. Overall, at this point no clear evidence exists that one particular opioid has a different adverse effect profile than another opioid. Patients may exhibit different sensitivities to different opioids because of individual variability in opioid receptors, pharmacokinetics, and metabolism. Inroads have recently been made in understanding which genetic variants may influence a particular person's response to opioids. For example, certain variants of the multidrug resistance 1 gene (formerly *MDR1,* now called *ABCB1*) or the gene encoding catechol-O-methyltransferase *(COMT)* are associated with CNS adverse effects, such as drowsiness or confusion.[123] A very promising recent approach to reducing opioid adverse effects involves identifying opioid agonists with "ligand biasing" of actions on opioid receptors that preferentially act via G proteins rather than via beta-arrestin signaling.[124]

Opioid-associated adverse effects may be also improved with a reduction in opioid dose, which may be achieved without loss of analgesic effect if a coanalgesic medication is added. For example, when gabapentin and morphine are combined they provide better analgesia from neuropathic pain at lower doses of each drug than either does as a single agent.[125]

Opioid-Induced Neurotoxicity. Opioid-induced neurotoxicity is typically encountered when opioid doses are rapidly increased, when high doses of an opioid are used, or in the setting of renal failure. The patient may describe increased sensitivity to pain (hyperalgesia), pain in response to nonpainful stimuli (allodynia), worsening pain despite increasing doses of opioids, or pain that appears to spread. Other findings of neurologic hyperexcitability such as myoclonus, delirium, or seizures may also be present. Opioid-induced hyperalgesia is likely due to accumulation of neurotoxic opioid metabolites such as M3G or hydromorphone-3-glucuronide. Such metabolites activate presynaptic calcium channels that release glutamate, which in turn activates NMDA receptors and depolarized postsynaptic neurons in the CNS.[126]

If signs or symptoms of opioid neurotoxicity develop, the opioid should be decreased or changed to one with potentially less neurotoxic effects, such as fentanyl or methadone. The addition of a nonopioid analgesic may lessen the amount of opioid required. An alternative mode of analgesia such as intrathecal, regional, or local analgesia may be used in place of systemic opioids. If needed, parenteral ketamine, an NMDA receptor antagonist, may also be initiated to reduce NMDA receptor-mediated neurotoxicity.[127]

Myoclonus is frequently relieved by a benzodiazepine such as diazepam. Opioids may also play a role in the development of delirium; the reader is referred to the section in this chapter dedicated to mental status changes.

Management of Opioid Overdose. Respiratory depression occurs as a result of opioid receptor blockade of CO_2 chemoreceptors in the medulla. The risk of respiratory depression from opioids is indeed small when opioids are dosed and titrated judiciously. Scenarios in which opioids may cause respiratory depression are the development of renal failure or a sudden decrease in pain, such as after a neurolytic block if opioid doses are not adjusted.

Respiratory depression characterized by hypopnea alone is not in and of itself an indication for opioid reversal with naloxone. In fact, administration of oxygen and reduction of the subsequent dose may be the only actions needed. For a true respiratory emergency, naloxone should be administered by (1) diluting the 0.4 mg/mL ampule in 10 mL saline solution and (2) administering 1 mL IV or subcutaneously every 3 minutes until respiratory depression improves. If the patient is taking long-acting opioids, repeated doses of naloxone or a naloxone infusion may be required, with the hourly dose being the dose initially required to overcome respiratory depression. Overadministration of naloxone will block opioid receptors, resulting in withdrawal that may be characterized by severe pain and sympathetic instability.

Adjuvant Treatments

Radiotherapy

Radiotherapy is commonly used to relieve pain such as localized bone metastases. In a review of 13 randomized trials in adults with painful bone metastases who received either radiotherapy or radioisotope injection for pain, it was found that 27% achieved total pain relief and 42% attained a 50% level of pain relief. The largest trial found that the median duration of complete pain relief was 12 weeks. A variety of fractionation schedules were used, and no clear difference between schedules was found.[128]

Antidepressants

TCAs and serotonin and norepinephrine reuptake inhibitors (e.g., duloxetine) may relieve neuropathic pain and are discussed in more detail later.

Steroids

Pain attributable to swelling, such as headache from increased intracranial pressure, bone pain, nerve pain from compression by a tumor, and hepatic capsular pain, may be responsive to steroids. A common starting dose is 10 mg followed by 4 mg four times a day in larger patients. Dosages of 10 mg/m^2 followed by 4 mg/m^2 four times a day can be used in smaller patients. If the response is favorable, the steroid dose should gradually be reduced to the lowest effective dose. A medication to provide concurrent gastric protection should also be prescribed.

Anticonvulsant Agents

Anticonvulsant agents control neuropathic pain by preventing peripheral nerve excitation. Carbamazepine has been widely studied for neuropathic pain such as trigeminal neuralgia. However, carbamazepine interacts with many other drugs and may suppress bone marrow function, limiting its usefulness in patients with cancer. Oxcarbazepine is a carbamazepine derivative that acts via use-dependent blockade of sodium channels. Overall, compared with carbamazepine, oxcarbazepine appears to result in fewer risks for hematologic, dermatologic, and hepatic complications. Hyponatremia can occur, and electrolytes should be monitored in the first weeks of therapy or with dose escalation. Gabapentin and pregabalin are newer anticonvulsants that lack such interactions and bone marrow toxicity. These agents target both excitatory and inhibitory neurotransmitters through inhibition of sodium and voltage-gated calcium channels.

Gabapentin may be sedating, requiring gradual initiation (i.e., a 5 to 7 mg/kg/dose by mouth three times a day, with a gradual increase every 3 days) and titration to effect. Reports of pediatric uses of gabapentin and pregabalin for treatment of chronic neuropathic pain are limited to case series. For any of the anticonvulsants, effects on mood, sedation, and mental clarity are quite variable.

Clonidine

Clonidine is an alpha-agonist drug that historically has been used to treat hypertension or opioid withdrawal. It may also be used for neuropathic pain or to enhance analgesia from opioids. Clonidine may be administered orally or transdermally, which is an additional benefit in the pediatric population. Clonidine has also been used in children for hyperactivity or steroid-associated psychiatric symptoms. Sedation is common.

Ketamine

Ketamine is an effective adjuvant analgesic that is useful for its opioid-sparing and opioid-sensitizing capabilities, particularly in persons experiencing difficult pain syndromes such as neuropathic pain.[129] Although the evidence is scant, reports exist of its usefulness in relieving refractory pain in children with cancer.[130] Ketamine may on occasion cause hallucinations and depersonalization/derealization. Such effects are more common in adults and may be prevented or treated with a benzodiazepine.

Invasive Approaches to Pain Management

In a small subgroup of patients, aggressive titration of analgesics and adjuvants still results in a circumstance of inadequate analgesia and/or intolerable adverse effects, including intolerable sedation. In some situations consideration of regional anesthetic approaches may be appropriate; the most common approaches are infusions of analgesics and local anesthetics via indwelling intrathecal, epidural, or plexus catheters. A number of considerations influence the choice of these methods, including the wishes of the patient and his or her surrogate in terms of balancing analgesia, alertness, and the risks and inconveniences of a technologic approach; availability of expert personnel for both catheter placement and ongoing management; and consideration of the nature of the pain, the expected course of the disease, and disease-related symptoms. Because a number of technical and management issues cannot be readily extrapolated from similar infusions in adults or from perioperative infusions in children, consultation with clinicians who have experience in these techniques is encouraged. In adults, a track record exists of using implantable programmable pumps that can be refilled at a frequency ranging from weekly to every several months. One study indicated benefits of these systems with regard to pain, quality of life scores, and even longevity.[131]

In children with cancer, it is generally necessary to combine small amounts of a local anesthetic along with opioids in the spinal infusion. Because of the relatively low potency and low solubility of existing local anesthetics, this requirement makes it impractical to use the programmable pumps commonly used in adults. Therefore in a majority of these cases, our preference has been to use implanted intrathecal ports rather than implanted pumps. The procedure to place these ports is performed in the operating room with use of general anesthesia while the patient is in the lateral position. The intrathecal catheters are advanced cephalad from spinal entry near L3-L4 under fluoroscopic guidance to position the tips near the spinal dorsal horn levels (rather than the exiting nerve root levels) relevant to the sites of greatest pain. The reader is referred to Figure 564 in the atlas by Clemente[132] for illustration of the spinal dorsal horn levels.

As an example, for refractory pain due to pelvic or lower extremity tumors predominantly involving lumbosacral dermatomes, we advance the catheter tips to a level around T11. Catheters are tunneled subcutaneously and connected to a port that is positioned over the lower ribs near the anterior axillary line.

In the setting of refractory pain due to advanced cancer, our view is that coagulopathy in most cases should not be regarded as a major contraindication to this procedure. If necessary, platelets and/or fresh-frozen plasma are infused immediately before and during the procedure as guided by coagulation parameters.

Use of indwelling ports is preferable for the sake of sterility and skin care. Ports are accessed with Huber needles similar to those used for IV ports. Dilute local anesthetics are generally required for adequate analgesia (particularly with movement), and they can generally be titrated in a manner that preserves reasonable lower body motor functioning. Depending on the adverse-effect profile seen with opioids and local anesthetics, other spinal analgesics may be included in the mixture, including clonidine and ketamine.

Although the epidural route can be used, our experience is that the intrathecal route is more reliable over a longer time frame because of several factors, including the development of adhesions or fibrosis in the epidural space over periods of months with use of high-concentration infusions and because of the phenomenon of tolerance to local anesthetics, which can be overcome very readily with intrathecal dosing but with much greater difficulty with prolonged epidural dosing. Clinicians' estimates of prognosis and longevity are often imprecise. Our general recommendation is that, if invasive approaches are being considered in the first place, the most versatile system available should be chosen to be implanted—that is, one most likely to work successfully for the short term (i.e., a few weeks) as well as longer term (i.e., months to a year) and least likely to require a repeat procedure. One potential early complication of this procedure is cerebrospinal fluid leak, leading to headache in the days after placement. In two cases we have returned to the operating room several days later to resolve this problem with a fluoroscopically guided epidural blood patch. The introduction of spinal analgesic medication and the corresponding adjustment of systemic analgesics require careful attention because of the potential for oversedation and even respiratory depression. Because the intensity of afferent nociceptive transmission is diminished by the spinal medications, the stimulating effect of this nociceptive activity on alertness and respiratory drive is also diminished.

Occasionally in patients who have a tumor that involves a single peripheral nerve or nerve plexus, indwelling tunneled catheters can be placed percutaneously along the nerve or in the plexus sheath. Our preference is to use a combination of ultrasound and nerve stimulation guidance. These peripheral and plexus catheters can be extremely helpful if the pain remains highly localized. In a majority of cases, however, the tumor spreads beyond these more limited distributions, and we have therefore generally favored intraspinal infusions because of greater versatility in covering pain arising from a broader area. For similar reasons, our general preference is to choose intraspinal drug infusions rather than neurolytic nerve blocks except in very restricted circumstances, such as the use of a neurolytic celiac plexus blockade for a tumor that is almost entirely restricted to the upper abdominal solid viscera. Celiac plexus blockade has a good track record for treatment of refractory pain due to pancreatic cancer in adults. It affects visceral innervation only and produces no somatic sensory or motor deficits. Adverse effects such as diarrhea or orthostatic hypotension tend to be relatively short-lived and tolerable. For children and adolescents, our preference is to perform this procedure with use of general anesthesia with the patient in the prone position, using alcohol as the neurolytic agent. We use a posterior approach with computed tomography (CT) guidance, in collaboration with an interventional radiologist. Interventional approaches for pain in children were recently reviewed.[133]

Psychological and Nonpharmacologic Approaches to Pain

Because of the multifactorial nature of the experience of pain, a multidisciplinary approach is often helpful in optimizing pain management. With use of psychosocial assessment it may be possible to identify and address factors that contribute to pain that analgesic interventions alone cannot address.

Depending on the developmental capacity of the child, interventions such as preparatory play, distraction, imagery, relaxation, deep breathing, hypnosis, and behavioral management can reduce anxiety and fear associated with pain. A child life specialist, psychologist, complementary medicine practitioner, or other specialist may be able to provide some of these interventions.

A variety of cognitive and behavioral approaches to pain and invasive procedures may be helpful to reduce pain and distress experienced by the child. In a study of 56 children aged 3 to 13 years, delivery of a cognitive-behavioral intervention was compared with preprocedure administration of diazepam or cartoon watching prior to bone marrow aspiration.[134] The cognitive-behavioral intervention consisted of breathing exercises, positive reinforcement, and imagery or distraction to provide the child with imaginative and cognitive tools to cope with procedural stress. Overall, children who received the cognitive-behavioral intervention had lower pulse rates and distress and pain scores when compared with children who either received diazepam or watched cartoons. However, during the actual aspiration procedure, no difference was found between groups, suggesting that it did not ameliorate distress associated with the intense experience of the actual procedure.[135] Cognitive behavioral therapy (CBT) does provide children with mechanisms for coping with distressing procedures and may explain why children who receive CBT display less distress after the procedure compared with children who receive an anesthetic via a mask but do not receive CBT.[136]

Hypnotherapy can be performed in children as young as 4 years.[137] Hypnosis can reduce procedural pain (e.g., from a bone marrow aspirate) and postoperative pain in children, as well as anticipatory nausea and dyspnea. In a randomized controlled trial of 30 children (ages 5 to 15 years) with cancer who were undergoing bone marrow aspiration, children who received either hypnosis or CBT reported less pain and anxiety compared with their baseline symptoms or control subjects who did not receive either intervention. Children who underwent hypnosis also demonstrated less procedure-related distress than did those in the other two groups.[138]

Music, art, and play therapy may also be helpful in reducing anxiety associated with procedures. For example, soft lullaby music reduces heart rates in children undergoing the application or removal of a cast.[139] Even when specific nonpharmacologic techniques are not employed, some behavioral strategies should always be used, including appropriately preparing the child, giving the child choices when possible, providing developmentally appropriate and honest explanations, and providing positive reinforcement. Patient education is also an important component of addressing pain.

Many patients find integrative therapies (i.e., therapies complementary to traditional medical approaches) to be of benefit in coping with stress, reducing the effects of treatment and illness, providing a sense of control, and enhancing quality of life.[140] In a survey of adults participating in cancer clinical trials, 63% used at least one type of integrative therapy, with an average use of two therapies per patient.[140] Few clinicians are aware of these practices and thus should routinely inquire about them.

Although many practices such as acupuncture, massage, and healing touch seem promising in reducing cancer-related pain, the evidence base supporting these therapies is weak. Barriers to the publication of such trials include issues of study quality and design such as small study size, high attrition rates, and lack of a comparison arm, particularly in fields where the placebo effect may be high.[141] Studies with adequate power and duration and sham controls are needed to evaluate the efficacy of these interventions for cancer-related pain.

Pediatric Cancer Pain Syndromes

Although pain should be approached with a systematic approach and the use of analgesics, including opioids and adjuvants, certain cancer-related pain syndromes may respond to particular treatments.

Tumor-Mediated Pain

GI obstruction may cause pain. Management of GI obstruction is discussed in the section entitled "Other Gastrointestinal Symptoms." Visceromegaly or invasion of organs, which often presents as a poorly localized, dull pain, is best treated with opioids, radiation, nerve blockade, or epidural/intrathecal techniques. Involvement of nerve or bone may result in neuropathic or bone pain, which is discussed later. Liver capsular pain may be alleviated by steroids.[142] Elevated intracranial pressure may present as headache and vomiting and may respond to steroids or surgical decompression. In situations in which inflammation is thought to contribute to pain, the pain may respond to steroids or NSAIDs.

Pain Related to Administration of Antineoplastic Therapy

Antineoplastic therapy may produce a variety of pain syndromes. Injection of chemotherapy into a peripheral vein may cause local transient pain or phlebitis. Extravasation of a vesicant such as vincristine or anthracycline may cause local pain, burning, swelling, and/or redness, as well as tissue necrosis. These symptoms are most likely to occur when the agent is injected peripherally. Preclinical data showed that dexrazoxane, a reversible topoisomerase II catalytic inhibitor, reduced the number, severity, and duration of wounds that developed in a dose-dependent manner after extravasation.[143] In a single-arm, open-label study of 53 humans with anthracycline extravasation, dexrazoxane was well tolerated. In this uncontrolled trial, one patient required surgical resection (1.8%).[144]

Intrathecal chemotherapy may cause arachnoiditis, which is associated with fever, headache, nuchal rigidity, nausea, and vomiting. A new liposomal formulation of cytarabine appears to have an increased risk of arachnoiditis in children, which can be mitigated with systemic dexamethasone.[145]

Prolonged steroid administration may result in avascular necrosis, which occurs most often in the hip.[146] NSAIDs may help provide relief for this painful condition, although if the pain is severe, opioid therapy may be indicated. Pamidronate is a bisphosphonate that holds promise in reducing symptoms and increasing function in children who have painful osteonecrosis due to steroid therapy for acute lymphoblastic leukemia (ALL).[147,148]

Bone Pain

Infiltration of bone is often experienced as a constant aching, which may be relieved by steroids, NSAIDs, or opioid analgesics. Isolated bone metastases may be treated with local treatments such as external beam radiation or surgical techniques such as vertebral body or long bone stabilization or other more invasive treatments for pain (see "Invasive Approaches to Pain Management"). Bisphosphonates, which reduce osteoclastic bone resorption, may be helpful when analgesics or radiotherapy are inadequate for the management of painful bone metastases.[149] Diffuse bone metastases may also be treated with radioisotopes, but radioisotopes may cause myelosuppression.

Bone pain may also be caused by filgrastim or pegfilgrastim.[150] Although the mechanism underlying such pain has not been clearly established, it is frequently attributed to filgrastim-stimulated marrow expansion. In a study of 100 adults receiving care in a community oncology practice, 79% experienced either moderate or severe bone pain due to use of pegfilgrastim. Pain was either diffuse or located in the lower extremities/hips or back. For persons with the most severe pain, the mean duration of pain was 2.8 days after the injection. NSAIDs provided relief for 74% of persons with moderate pain. Some persons with severe pain received opioids, but opioids provided relief in only 45% of patients. Interestingly, patients with lymphoma who were receiving concurrent steroids as lymphoma-directed therapy did not have significantly less bone pain.

Filgrastim-induced bone pain has not been well studied in children, although anecdotally it appears to occur less frequently in children than in adults. In a relatively small study of 28 children with cancer who received pegfilgrastim (100 μg/kg with a maximum dose of 6 mg for a total of 126 doses) after myelosuppressive chemotherapy, four children reported bone pain.

Although use of antihistamines to treat filgrastim-associated bone pain has been reported,[151] no clinical trials have been performed to evaluate this practice. Until evidence indicates that antihistamines reduce this type of bone pain, antihistamines should not be used at the exclusion of established analgesic practices.

Mucositis

Mucositis is a common problem for children after chemotherapy, radiation, or bone marrow transplantation. It is particularly problematic in children undergoing high-dose chemotherapy or head and neck radiotherapy. Mucositis is associated with increased risk of infection and may impair intake of adequate nutrition. It usually self-resolves within 14 days or upon recovery of the bone marrow. The WHO has developed a mucositis rating scale that ranges from 0 (no visible evidence of mucositis, no pain, able to eat solids, and able to drink) to 4 (erythema, ulceration present, significant pain, and inability to eat or drink). Prophylactic antiviral or antifungal therapy does not decrease the incidence of mucositis. However, superinfection should be considered and cultures should be obtained when mucositis appears to be more severe or prolonged than anticipated.

Historically the mainstay of pain control for mucositis has been parenteral opioid therapy, usually via PCA. This mechanism of analgesia delivery is both safe and effective for this purpose.[112] An adjuvant mouthwash containing diphenhydramine, 2% viscous lidocaine, and liquid antacid (e.g., Maalox) in a 1:1:1 formulation may be used in children older than 2 years who can spit out the medication rather than swallowing it. Topical application of straight viscous lidocaine carries the risk of systemic absorption if the mucositis is widespread. Although the true risk of aspiration due to local anesthesia of glottic structures is unclear, some centers avoid using this strategy because of this concern. A supersaturated calcium phosphate mouth rinse moistens and lubricates the oral cavity. Although results of studies of this agent have been mixed, the majority of studies support its use to reduce the severity/duration of mucositis and the pain associated with it. The Children's Oncology Group is currently conducting a study of this rinse in preventing mucositis in children who are undergoing hematopoietic stem cell transplantation.

Other measures to alleviate mucositis include regular administration of oral sucralfate during chemotherapy, low-dose laser therapy, and gum chewing.[152-154] Results of studies evaluating the efficacy of the free radical scavenger amifostine in reducing mucositis have been inconsistent.[155] Severe mucositis can also cause abdominal pain, which is best treated with opioids. Perineal pain due to mucositis may also be addressed with a topical barrier cream to soothe and protect the area.

Recent advances in the understanding of the pathogenesis of mucositis have led to the development of targeted therapies. For example, palifermin is a keratinocyte growth factor that mediates epithelial cell growth and reduces epithelial cell apoptosis, factors that both appear to be important processes in the evolution of mucositis. Palifermin reduces mucosal injury as manifested by decreased mucositis duration and severity and a reduced need for analgesics and parenteral nutrition in adults undergoing high-dose chemotherapy and radiotherapy requiring peripheral blood stem cell rescue. In one study of adults undergoing high-dose therapy with autologous stem cell rescue, the incidence of WHO grade 4 mucositis was reduced from 62% to 20% ($P < .001$).[156]

The role of L-glutamine in mucositis has also been recently investigated. Depletion of L-glutamine is associated with epithelial damage, and increased levels are associated with healing. The role of uptake-enhanced L-glutamine suspension (AES-14) in reducing mucositis has recently been studied. In a placebo-controlled crossover study of 326 women undergoing chemotherapy for breast cancer, AES-14 reduced mucositis incidence and severity.[157] In addition, AES-14 demonstrated a carryover effect, with patients receiving AES-14 before placebo having a lower risk of mucositis.

Neuropathic Pain

Neuropathic pain may occur from infiltration or compression of nerves, nerve damage from surgery, herpes zoster, or adverse effects from antineoplastic therapies such as vinca alkaloids, cisplatin, oxaliplatin, or bortezomib. Children often describe it as burning or shooting pain, and it may be accompanied by dysesthesia or hyperalgesia.

Neuropathic pain may be related to chronic pain states whereby chronic afferent input into the dorsal horn of the spinal cord leads to a hyperactive state. Mediators of this condition are excitatory amino acids, such as glutamate, which bind to the NMDA receptor. The NMDA/glutamate receptor is a calcium channel involved in opioid-resistant pain, neuropathic pain, allodynia, and hyperalgesia. NMDA receptor binding may lead to lasting increases in neuronal excitability, leading to persistence of neuronal hyperactivity. The end result of such a phenomenon is hyperalgesia, allodynia, spontaneous pain, and phantom limb pain, even after the painful stimulus has resolved. Methadone, with its NMDA receptor antagonist properties, may be the most appropriate opioid for neuropathic pain. However, no clear evidence from studies in humans shows that methadone is superior to other opioids in treating neuropathic pain.[158] In addition, other approaches such as nerve blocks or adjuvant NMDA receptor antagonists may disrupt ongoing nociceptive input and neuronal hyperexcitability.

Most therapies for neuropathic pain have been evaluated in non–cancer-related neuropathic pain syndromes such as diabetic neuropathy. Medications for neuropathic pain include TCAs and the newer atypical antidepressants venlafaxine and duloxetine. TCAs often relieve neuropathic pain more quickly and at lower doses than are required to treat depression. TCAs reduce neuropathic pain by inhibiting serotonin and norepinephrine uptake, which increases transmission of inhibitory signals in the spinal cord. For children experiencing disturbed sleep, amitriptyline, a TCA that leads to greater sedation, may be a good choice. However, amitriptyline also has more anticholinergic effects such as xerostomia and constipation, in which case nortriptyline is an alternative TCA.

Duloxetine is the first antidepressant to be approved by the U.S. FDA for treatment of neuropathic pain, and in a recent multicenter randomized placebo-controlled crossover trial, it was demonstrated to reduce chemotherapy-induced painful peripheral neuropathy.[159] Anticonvulsants such as topiramate, pregabalin, or gabapentin may also be effective.[125,160,161] In the cancer population, gabapentin effectively reduced tumor-related neuropathic pain in a randomized controlled study of adults already receiving opioids, with lower average pain intensity scores and less dysesthesia in the gabapentin group.[162] In some instances when tumors incite pain because of spinal cord compression, dexamethasone may reduce pain.[163] Other interventions such as topical lidocaine or capsaicin, transcutaneous electrical nerve stimulation, surgical decompression, or nerve blocks may also relieve neuropathic pain.

Phantom Limb Pain

Phantom limb pain is a common phenomenon in children who undergo amputation of an extremity.[164] It may be experienced as either stump pain or the type of pain experienced preoperatively, and it appears to improve over time.[164,165] Phantom limb pain appears to be associated with preoperative limb pain.[164] For this reason it is best approached with preemptive regional anesthesia. In our practice, regional anesthesia is used widely for anesthetic and analgesic management of amputations in children. The widespread use of ultrasound guidance has increased the reliability of continuous peripheral nerve blockade via indwelling catheters.

Additional measures to treat phantom limb pain include anticonvulsants, TCAs, and topical agents such as Lidoderm. Some small series have reported success with gabapentin[166] and topiramate for phantom limb pain.[167] A preliminary observational study found that use of a prosthesis to support limb use was associated with reduced phantom limb pain when compared with cosmetic prosthesis use.[168] A few studies suggest that therapy with mirrors may relieve phantom limb pain, although the limitations of these studies, including small sample size, preclude definitive conclusions.[169,170]

Pain Related to Graft-Versus-Host Disease

Graft-versus-host disease (GVHD) may cause a variety of pain syndromes. It is a common cause of abdominal pain in children undergoing bone marrow transplantation.[171] Along with diarrhea, nausea/vomiting, weight loss, dysphagia, and early satiety, abdominal pain/cramping may occur in gut GVHD.[172] Antimuscarinic/anticholinergic agents such as scopolamine may reduce colic from smooth muscle spasms. However, gut GVHD may be so severe that opioids are required for analgesia.[113]

Oral GVHD usually does not cause pain. Development of oral pain is associated with ulceration or involvement of the soft palate.[173,174] When evaluating pain in the setting of oral GVHD, one should also consider a concomitant infection such as herpes simplex virus or candidiasis. Oral GVHD pain is usually reduced with GVHD-directed treatment such as topical steroids or topical FK506 rinses. Pain associated with vulvovaginal GVHD may also respond to topical steroids or topical cyclosporine.[175,176] Other types of GVHD, such as myositis or fasciitis, may require systemic analgesia.

Postoperative Pain

A broader discussion of treatment of postoperative pain in children and adolescents than that presented here can be found elsewhere.[177,178]

Cancer surgery is often distressing and anxiety provoking for children and their parents. Unless specifically contraindicated, anxiolytic premedication with benzodiazepines should be considered routine, using oral or IV routes as appropriate. For patients who were treated with opioids on a regular basis before surgery, it is necessary to increase postoperative analgesic dosing accordingly. It is a common mistake to select routine parameters for opioid infusions or PCA for these patients, which invariably results in underdosing and inadequate analgesia.

For major tumor resections in the lower extremities, pelvis, abdomen, and thorax, we make extensive use of epidural infusions for postoperative analgesia. Epidural analgesia in children requires specific training regarding the technical aspects, as well as pediatric-specific management protocols and a level of acute pain service coverage that permits optimal dose adjustment. For patients receiving epidural infusions who were opioid tolerant before surgery, it may be necessary to provide a systemic opioid along with an epidural opioid postoperatively (despite a widespread "taboo" against this combination); alternately, larger than usual dosing of epidural opioids, the addition of epidural clonidine, or other approaches may be necessary to account for the patient's preexisting opioid tolerance, which may be accompanied by hyperalgesia. Peripheral nerve and plexus catheters placed via ultrasound guidance are increasingly being used for surgery on the limbs. For thoracotomies, ultrasound-guided continuous paravertebral catheters are a promising alternative to thoracic epidural catheters.

Procedure-Related Pain

Brief procedures involving the use of needles, including venipunctures, IV cannulation, lumbar punctures, and bone marrow biopsies and aspirates, are a major component of cancer care and a major source of distress for patients. Approaches to management of these interventions should be individualized, based on consideration of the child's age, temperament, coping style, and past pain experiences, as well as the intensity of the procedure (e.g., bone marrow biopsy is more painful than a simple venipuncture).

Explanations provided prior to procedures should be tailored according to the child's age, developmental status, and coping style. The presence of the parents can be helpful, especially when the parents have been coached to help facilitate positive coping. Parents should be present to provide support, not to hold the child or assist the clinicians.

A variety of products are available to provide needle-free skin analgesia. These products include local anesthetic creams such as eutectic mixture of local anesthetics (EMLA), ELA-Max, tetracaine gel (Ametop), patches such as Synera, needleless injection systems such as Zingo, and lidocaine iontophoresis. These products differ in their onset time, propensity for vasodilation or vasoconstriction, cost, and availability in different countries. In a busy clinic, use of these topical anesthetic techniques is facilitated by standing order policies so they can be applied at an appropriate time before the planned procedure.

Several cognitive-behavioral approaches have been shown to be effective in reducing a child's procedure-related distress, including hypnosis, guided imagery, and related approaches to achieving a relaxed or dissociated state. These approaches have the virtue of safety and generalizability. A patient who learns these techniques for one setting can apply them to other situations.

Conscious sedation, deep sedation, or brief general anesthesia can be very effective in alleviating the pain and distress of lumbar punctures and bone marrow biopsies and aspirates. The approach chosen will depend in part on the individual patient, the intensity of pain involved in the procedure, the degree of immobility required (e.g., for radiation therapy or magnetic resonance imaging), and available resources.

Considerable variation exists in the choices of drugs, the depth of sedation, and the personnel involved in different aspects of sedation. In some hospitals a two-tiered approach is taken, with lower risk patients receiving sedation administered by oncologists and nurses and higher risk patients cared for by pediatric anesthesiologists.

Other hospitals use a different two-tiered approach, with sedation for low- to intermediate-risk patients being administered by nurses and pediatric subspecialists from a sedation service who have specific expertise (e.g., pediatric intensivists or pediatric emergency physicians) and utilization of pediatric anesthesiologists to care for higher risk patients, those having more extensive procedures, or those requiring higher degrees of immobility. For example, for a cooperative, relatively healthy 12-year-old undergoing a lumbar puncture, a regimen that involves conscious sedation with midazolam and fentanyl and topical local anesthesia followed by local anesthetic infiltration is likely to be safe and effective. Conversely, a 2-year-old with a history of a very difficult to manage airway and cardiomyopathy who is undergoing bone marrow aspiration, biopsy, and a lumbar puncture would be at higher risk and therefore might be referred for management by a pediatric anesthesiologist.

In our view, regardless of local decisions about which specific specialists are involved in which procedures, pediatric oncologists need to advocate for sufficient institutional resources to ensure that effective and safe approaches to conscious sedation and general anesthesia are available for all children with cancer. Some general recommendations for sedation programs are listed in Box 71-1.

More detailed discussions of individual drugs and outcomes of pediatric sedation may be found elsewhere.[179,180]

Reassessing Interventions for Pain

Careful reassessment to determine response to therapy is a key component in effectively addressing pain. In addition to reducing pain, interventions seek to reduce distress and functional impairment and enhance quality of life. Pain relief measures do not necessarily achieve all of these goals. For example, in one survey of adults with non–cancer-related pain, even when the degree of pain was controlled for, persons receiving opioid therapy did not have improved quality of life or improved function.[181] Therefore in addition to evaluation of whether pain relief is attained, determination of whether increased functional capacity and increased quality of life is achieved is crucial in symptom management.

Box 71-1 **Recommendations for Pediatric Oncology Sedation Programs**

1. A standardized preprocedure history and physical should be performed to identify factors that might modify risk (e.g., airway anomalies, respiratory difficulties, and cardiac compromise).
2. Use of procedure checklists should be encouraged.
3. Nothing by mouth guidelines should be consistent with those recommended for children undergoing general anesthesia.
4. Clinicians who are performing the procedure should have undivided attention during the procedure (e.g., their beeper and phone should be carried by someone else), and they should ensure that all necessary supplies (including kits, sterile supplies, chemotherapy, and tubes) are already in the room before bringing the child into the room or initiating sedation.
5. Children receiving sedation should receive continuous monitoring, including a dedicated observer, continuous use of pulse oximetry, and regular recording of vital signs.
6. All procedure locations should have at least the following supplies, equipment, or systems at hand:
   a. Wall or tank oxygen supplies
   b. Wall or portable suction devices
   c. Monitoring equipment
   d. Airway equipment, including bags and suitably sized masks, laryngoscopes, endotracheal tubes, oral airways, and laryngeal mask airways
   e. An emergency cart, such as a code cart
   f. Communication protocols (often assisted by a code button or phone system)
7. After the procedure, children require observation until they meet standardized recovery criteria, and often for a period of time thereafter. During recovery, and especially when they no longer appear sedated, children remain at significant risk for injuries caused by falling, hitting their head on bed rails, and so forth.
8. Observation and administration of medications should be performed by a clinician with no additional responsibilities—that is, not by the clinician performing the procedure. These clinicians should have training and competency in pediatric acute care and pediatric airway management.
9. Clinics and hospitals performing pediatric sedation should track outcomes related to efficacy (from a child-centered viewpoint) and safety to facilitate system-based improvements in quality of care.

Barriers to Effective Pain Management

Increasing interest in pain and pain treatment in recent years has resulted in a better understanding of pathophysiologic mechanisms of pain, better treatment options, and greater availability of treatment for pain. However, these advances have not necessarily resulted in a reduced prevalence of pain in patients with cancer.[182]

This paradox is due in part to the multitude of barriers to effective pain management. Clinician-related barriers include a focus on cure at the exclusion of attention to symptoms, lack of familiarity with pain management, fear of either regulatory repercussions for prescribing opioids or diversion of the medications to persons for whom the opioid is not prescribed, and underappreciation of the multifactorial nature of the experience of pain. Patient-related factors may include fear of addiction; fear of adverse effects, including respiratory depression; fear that treating pain with opioids is equivalent to "giving up"; and the misperception that opioids should be "saved" for severe pain.

Educational strategies for clinicians and families alike are likely to surmount many of these barriers to pain management. In addition, partnership with the child and family may enhance attention to this important issue and provide added opportunities for addressing barriers to treating pain adequately. For example, a randomized clinical trial tested the effectiveness of the PRO-SELF Pain Control Program, which actively involves adult patients and families in the pain management plan; findings included decreased pain intensity scores, an increased number of appropriate analgesic prescriptions, and increased analgesic intake in oncology outpatients who had pain from bone metastasis when compared with standard care.[183] Such an approach is endorsed by the American Pain Society and is likely to contribute greatly to overcoming barriers to successful pain management.

NAUSEA AND VOMITING

Pathophysiology

Vomiting may be caused by a wide variety of triggers, including motion, insult to the GI tract, hormonal changes, medications, and emotions. Vomiting is a complex process that involves both the central and peripheral nervous systems, with both biologic and psychological mechanisms playing a role.

During the past three decades strides have been made in understanding the pathophysiologic components of

Figure 71-3 The pathogenesis of chemotherapy-induced nausea and vomiting.

nausea and vomiting and in the development of agents aimed at them. Investigations have focused primarily on chemotherapy-induced nausea and vomiting (CINV). Prior to the 1990s, dopamine was the major neurotransmitter recognized as being important in mediating CINV, and dopamine blockade was the mainstay of therapy for CINV.

Vomiting is mediated by the vomiting center in the medullary lateral reticular formation. This center is not a discrete entity but instead is a group of loosely organized neurons in the medulla that are activated in a sequential manner during emetogenesis.[184,185] Sources of afferent input to the nucleus tractus solitarius in the vomiting center include the chemoreceptor trigger zone (CTZ), the viscera (via vagal and sympathetic afferents), the midbrain, the vestibular system, and the cerebral cortex (Fig. 71-3). Vomiting occurs when the vomiting center emits coordinated efferent impulses to several targets including the diaphragm, abdominal wall musculature, esophagus, and stomach.

Chemotherapy-Induced Nausea and Vomiting

Chemotherapy can lead to nausea and vomiting through several mechanisms. One mechanism is by stimulation of the CTZ, which lies in the area postrema, in the floor of the fourth ventricle. Although the CTZ is part of the CNS, it contains chemoreceptors outside the blood-brain barrier that can detect emetogenic agents present in the circulation, as well as in the spinal fluid. However, evidence suggests that chemotherapy stimulates the CTZ indirectly because (1) it is unlikely that the CTZ has specific receptors that are activated by each type of chemotherapy agent; (2) the latency time to the onset of emesis is not compatible with direct action of the drugs on the CTZ; and (3) vagotomy and sympathectomy prevent cisplatin-induced emesis in the ferret, indicating that these inputs are needed for chemotherapy-induced vomiting to occur.[186,187]

Chemotherapy can also stimulate the vomiting center directly.[184] In addition, chemotherapeutic agents can stimulate the gut, leading to release of serotonin. This release in turn stimulates the vagus nerve, which activates the vomiting center, either directly or via impulses to the CTZ.[188] The central cortex may also be involved in CINV by mediating emotions such as anxiety that play a role in the genesis of nausea.

Several neurotransmitter pathways are known to play a role in nausea and vomiting. Whereas histamine and muscarinic receptors are prominent in vomiting associated with motion sickness,[189] serotonin, dopamine, and substance P appear to be particularly important in CINV.[190] Central blockade of the D2 subtype of dopamine receptors in the area postrema and vomiting center is the mechanism of action of antidopaminergic antiemetics such as metoclopramide. It was later found that in addition to dopamine receptor antagonism, metoclopramide was an antagonist of the 5-hydroxytryptamine 3 (5-HT3) receptor,[191,192] prompting interest in the role of this receptor in nausea and vomiting.[184]

Serotonin is produced by enterochromaffin cells in the gut and is also found in multiple locations in the CNS. Several observations in both animals and humans confirmed that serotonin plays a major role in acute CINV. Cisplatin and cyclophosphamide-induced vomiting in the ferret was drastically reduced with the administration of intravenous, intraperitoneal, or intracerebral injection of serotonin S3 receptor antagonists.[193] Serotonin receptor blockers and serotonin receptor blockade inhibited chemotherapy-induced vomiting in ferrets[186,194-197] and in other animal systems.[198,199] Depletion of serotonin stores was shown to also prevent cisplatin-induced vomiting.[200]

In humans, studies by Cubeddu et al.[201] demonstrated that strongly emetogenic regimens containing cisplatin or dacarbazine resulted in a marked increase in serotonin metabolites in plasma and urine with a time course similar to CINV symptoms in patients. In addition, treatment with a serotonin synthesis inhibitor inhibited both cisplatin-induced vomiting and increases in serotonin metabolites.[201] The relationship between other chemotherapeutic agents and markers of serotonin metabolism has been further explored, with more emetogenic regimens resulting in higher serotonin metabolite levels.[201] Chemotherapeutic agents appear to be toxic to the enterochromaffin cells lining the upper small intestine, resulting in generation of free radicals and release of serotonin.[187]

5-HT3 receptors are present in the GI tract as well as vagal afferents. They are also found throughout the human brainstem, including a high concentration in the CTZ.[202] Serotonin antagonists injected into the area postrema inhibit cisplatin-induced emesis in the ferret,[193] but it appears that 5-HT3 receptor antagonists also exert their antiemetic effect at the level of the peripheral nervous system via serotonin blockade in the vagal nerve.[203,204]

Substance P, which binds to the tachykinin neurokinin NK1 receptor, has more recently been implicated in mediating vomiting. Substance P is a neuropeptide found in both the CNS and in the GI tract. Because of its localization pattern and its ability to induce vomiting when administered intravenously, substance P was suspected to play a role in the genesis of vomiting.[205] NK1 receptor antagonists appeared promising in that they inhibited vomiting induced by a range of agents known to produce vomiting by both central and peripheral mechanisms in the ferret.[206,207] The site of antiemetic action of NK1 receptor antagonists has not yet been clearly defined. It may occur peripherally, at the level of vagal motor neurons that control relaxation of the gastric fundus.[185] Investigation of the time course of the antiemetic effects of a 5-HT3 antagonist and the NK1 receptor antagonist aprepitant indicates that serotonin may mediate the early vomiting process (within the first 8 to 12 hours of cisplatin administration), whereas later vomiting may be mediated by the binding of substance P to NK1 receptors.[203]

Classification of CINV

Acute and Delayed CINV. Acute CINV, also known as posttreatment CINV, is traditionally defined as nausea and vomiting that occurs within the first 24 hours after administration of chemotherapy. Delayed CINV occurs 24 hours after chemotherapy and may last up to 5 days. Delayed CINV is typically associated with certain chemotherapeutic agents such as cisplatin and peaks 48 to 72 hours after administration of chemotherapy.[208] The incidence of delayed CINV is as high as 89% in patients who receive cisplatin-based chemotherapy without antiemetic prophylaxis.[209] The incidence of delayed CINV in patients who do receive antiemetic prophylaxis is as high as 73%.[210]

Because not all acute CINV antiemetics are effective for delayed CINV and specific treatment for delayed symptoms may not be prescribed, delayed CINV may be more severe than acute CINV. The recent introduction of the NK1 receptor antagonist aprepitant has provided new options for controlling delayed CINV. However, it remains clear that the single best predictor of delayed CINV is acute CINV and that *control of acute CINV is a key factor in preventing delayed CINV*.[208,211,212] For example, in a cohort of 705 patients receiving chemotherapy for the first time, when acute CINV was completely controlled with ondansetron plus dexamethasone, 92% had complete control of delayed CINV. However, of the patients who did have acute CINV, only 41% had complete control of delayed CINV.[212]

Although some pharmacologic agents to control delayed CINV have been developed, lack of recognition of this problem remains a major barrier to its effective management. Grunberg et al.[213] demonstrated that in a cohort of patients receiving moderately emetogenic chemotherapy for the first time, clinicians overestimated control of CINV, and this discrepancy was particularly notable for delayed CINV, in which case control of symptoms was overestimated by 21% to 28%. More than 75% of clinicians underestimated the incidence of delayed CINV.[213] This misperception may in part explain the observation that fewer than half of persons who experience delayed CINV receive adequate prophylaxis that conforms to established guidelines.[214] Given the extent to which delayed CINV negatively affects the lives of persons undergoing chemotherapy,[215] improved practice, in conjunction with pharmacologic advances, is needed to reduce suffering from delayed CINV.

Relatively little information has been published regarding delayed vomiting in children. Pinkerton and colleagues[216] found that of 27 children who received cisplatin, cyclophosphamide, or carboplatin and ondansetron, 9 (33%) experienced delayed emesis. In a larger prospective study of pediatric patients who did not receive antiemetics during the delayed phase after chemotherapy, two of six children (33%) who received highly emetogenic antineoplastics (cyclophosphamide, cisplatin, or carboplatin) and 12 of 110 children (11%) who received other chemotherapeutic agents experienced delayed vomiting, although the accuracy of the incidence of delayed vomiting in the “high risk” group is limited by the small number of children in that group.[217] As has been appreciated in adult patients, children who vomited in the acute phase were significantly more likely to have delayed vomiting (45%) compared with children who did not experience significant acute vomiting (13%). In addition, chemotherapy lasting 2 or more consecutive days was associated with a significantly higher rate of delayed vomiting (39%) compared with chemotherapy administered on a single day (13%). In our experience, many children experience delayed CINV.

Anticipatory Nausea

Anticipatory nausea and vomiting is a conditioned response that occurs in anticipation of planned chemotherapy when vomiting has been poorly controlled in previous cycles. In adults, anticipatory nausea and vomiting occurs in one quarter of adults receiving chemotherapy[218] and is associated with higher anxiety, a history of severe acute CINV, and a history of delayed CINV.[218-221]

A similar pattern is seen in the pediatric population, with the severity of distress from nausea/vomiting, greater expectation for severe nausea/vomiting, and the severity of the nausea/vomiting that is actually sustained all corresponding with a higher likelihood of anticipatory CINV.[222-224] Anticipatory nausea/vomiting is most likely to develop within the first 4 months of therapy, usually occurs hours before treatment, and is most severe at the actual time that chemotherapy is administered.[222] Anticipatory nausea and vomiting in children appears to have features consistent with a conditioned response. These features suggest that this type of nausea and vomiting is a learned response, which explains why it is refractory to typical antiemetics.

Measurement and Assessment

Measurement. Although nausea and vomiting are often lumped together, as in the term "CINV," they may be regarded as two distinct phenomena. Nausea may be accompanied by physiologic changes such as pallor, sweating, or feeling hot or cold, but it is essentially a subjective experience that is measured by patient report. For this reason nausea cannot be studied in models other than humans. On the other hand, vomiting can be objectively measured. For this reason it is invariably used as the outcome of choice when evaluating interventions for nausea and vomiting. Complete control of CINV is a frequently used outcome and is defined as the absence of any vomiting for a defined period after administration of chemotherapy. That being said, vomiting does not always accompany nausea, and changes in vomiting do not necessarily reflect a concomitant change in nausea.

Although they can occur together, nausea occurs more frequently than does vomiting.[210,213,225] Much attention has been focused on the prevention of vomiting, which is an important goal because previous uncontrolled vomiting may stimulate anticipatory vomiting in subsequent cycles of chemotherapy. However, nausea is also an important symptom to assess and control because it too impairs functioning and quality of life, even in the absence of vomiting.[215,226-229] Finally, although advances such as the 5-HT3 receptor antagonists may have improved chemotherapy-associated vomiting, related posttreatment nausea has not improved.[230] For all these reasons, attention to both nausea and vomiting is needed. Research that reports only vomiting as an outcome is a limited endeavor, and interpretations of assessments that rely solely on vomiting should be made with care.

Instruments have been developed to measure the subjective phenomenon of nausea in adults.[231,232] Instruments to assess nausea in children, including children who are preverbal, have been described but are not in widespread use.[233,234] One strategy for assessing nausea in children is to have them use a simple analogue or numeric scale to rate the severity of their nausea. It is known that children 5 years and older can reliably use a color analogue scale to report the severity of their pain[235] and that children 7 years and older can report pain with a visual analogue scale[31] or a numeric scale, and thus it is likely that they can report their nausea with similar reliability. A nausea scale of 0 to 10 with six faces (the Baxter Retching Faces BARF scale) for use in children ages 7 to 18 years who have nausea for a number of reasons has recently been demonstrated to have convergent and discriminant validity, as well as responsiveness.[236]

Hinds et al.[237] have shown that a symptom distress instrument that includes nausea assessment, which was designed for adults, is reliable and valid in adolescents with cancer. Other symptom distress scales that include nausea assessment, most notably the Memorial Symptom Assessment Scale, are also reliable and valid in children.[3,4]

Within the pediatric population, parental report is also an important source of information when assessing nausea and vomiting. In one small study of CINV, parent-child dyads were found to have a moderate to strong association when reporting symptoms of nausea and vomiting.[238] Studies by Zeltzer et al.[239,240] have also showed a high degree of correlation between parental and child reports of nausea, although Tyc et al.[241] have found that parents tend to underestimate their child's nausea.

Assessment. When nausea and vomiting in patients with cancer are considered, attention is often focused on CINV. When evaluating a patient with nausea/vomiting, however, it is imperative that other causes be considered in the differential diagnosis.

A full assessment of a patient with nausea and vomiting that extends beyond quantification of the severity of the symptom permits the generation of a complete differential diagnosis. Only in this way can all possible mechanisms and therefore all potentially efficacious interventions be entertained.

Features such as whether the nausea and vomiting is acute or chronic and intermittent or constant, along with whether it is associated with any particular factors, are important to consider. Other elements of the history, such as whether vomiting is projectile, bowel patterns, current medications, and prior history of nausea and vomiting, can also be helpful in delineating the cause and therefore finding potentially effective interventions. For example, obtaining a history that suggests constipation as the cause of nausea and vomiting will lead to a workup and treatment plan that is entirely different than if the cause is suspected to be chemotherapy or labyrinthitis.

Another important component of the history is an assessment of the impact of the symptom on the patient's

Box 71-2 Patient-Related Risk Factors for Developing Chemotherapy-Induced Nausea and Vomiting

- History of previous chemotherapy and prior chemotherapy-induced nausea and vomiting
- Prechemotherapy nausea
- Prechemotherapy anxiety
- Female sex
- History of motion sickness
- Low performance status
- Low social functioning

daily functioning and quality of life. Specific instruments to address these aspects have been developed, such as the Morrow Assessment of Nausea and Emesis, which is a self-report form that allows adults to assess their experience with acute, delayed, and anticipatory CINV.[242]

Predictors of Nausea and Vomiting

The likelihood of CINV development and CINV severity is determined by both treatment-related and patient-related factors (Box 71-2). The particular agent used is the primary treatment-related risk factor for CINV, but higher dosages of the agent, shorter infusion rates, combinations with other agents, and repeated cycles of chemotherapy can also increase the risk of CINV.[204,243,244] When combination chemotherapy is given, antiemetics should be prescribed based on the most emetogenic chemotherapy drug and with the consideration that some combinations may potentially act synergistically in creating CINV.

Patient-related factors, as determined in the adult population, also appear to affect the risk for developing CINV (Box 71-2).[226,245,246] In one multivariate analysis, low social functioning, prechemotherapy nausea, and female sex were found to be predictive of more severe CINV.[226] Patients with a history of vomiting in a previous cycle are at greater risk of vomiting with the subsequent cycle[247] in part, perhaps, because of anticipatory vomiting. Use of patient-reported outcomes from previous chemotherapy cycles is critical when prescribing antiemetics. An assessment of the intended treatment, as well as the patient's individual risk factors, may help determine which patients are more at risk for the development of CINV and therefore in need of more intensive prophylaxis or rescue therapy.

Principles of Pharmacologic Therapy

Prevention of acute CINV is a key element in reducing delayed CINV. Because (1) the development of anticipatory CINV is based on prior experience, (2) severity of acute CINV predicts delayed CINV severity, and (3) rescue therapy is inadequate once nausea and vomiting have developed, the best approach to CINV and other situations in which nausea and vomiting may develop (e.g., in the postoperative period) is to prevent these symptoms from occurring in the first place. Although it is best to take a targeted approach based on the inciting cause and the suspected underlying pathophysiology and/or evidence demonstrating superiority of certain agents or classes in different situations, it is not always possible to know which agent to choose first. Guidelines for the initial choice of antiemetics, as well as dosing, are provided in Tables 71-2 and 71-3. In this situation, use of one (or two) agents with titration of the dose and the addition of other agents if necessary might be the best strategy. For CINV, which is thought to be mediated through several pathways, a combination of antiemetics is usually warranted. This approach is particularly necessary with use of highly emetogenic chemotherapy, in which case monotherapy is almost always insufficient.

Drugs used to manage CINV include true antiemetics and adjuvants. Adjuvant medications may be used to allay anxiety, induce amnesia, or induce sleep. Although many of these agents have been investigated in adults, evidence regarding their use in children, including optimal dosing and potential adverse effects, is frequently much more limited. When evidence regarding dosing in the pediatric population is available, it is presented in this chapter. However, in many circumstances we must rely on evidence from adult studies and extrapolate appropriate dosing. Furthermore, guidelines and standard practices in

TABLE 71-2 Schematic Approach to Chemotherapy-Induced Nausea and Vomiting*

Type of CINV	Prophylaxis	Breakthrough[†]
Acute CINV		
High risk	5-HT3 receptor antagonist Dexamethasone Aprepitant[‡] Lorazepam ± scopolamine patch, metoclopramide, or cannabinoid if needed	Same as prophylaxis, initially as needed, then scheduled
Moderate or low risk	5-HT3 receptor antagonist Dexamethasone ± lorazepam, scopolamine patch, metoclopramide, or cannabinoid if needed	
Delayed CINV	Ondansetron Aprepitant Dexamethasone ± metoclopramide, cannabinoid, as needed	Same as prophylaxis, initially as needed, then scheduled
Anticipatory CINV	Prevention of CINV Lorazepam Nonpharmacologic approaches	Lorazepam

CINV, Chemotherapy-induced nausea and vomiting; *5-HT3,* 5-hydroxytryptamine 3.

*Points to consider:

- Choose appropriate prophylactic antiemetics based on emesis risk, determined by patient-related risk factors and the emetogenicity of the chemotherapeutic agent(s) being used.
- Assess the effect of the antiemetic regimen regularly.

[†] If breakthrough CINV occurs, strategies may be to (1) add a new agent, (2) change the dose or schedule of antiemetics in use but not already maximized, or (3) change administration of existing "as-needed" antiemetics to scheduled administration. In addition, the prophylaxis regimen for subsequent chemotherapy cycles should be augmented.

[‡] If ≥12 years of age.

TABLE 71-3 Classes of Antiemetics, Dosing, and Routes of Administration

Class	Dose and Route	Indication	Notes
5-HT3 Receptor Antagonists			
Ondansetron	0.15 mg/kg dose PO every 8 h or 0.45 mg/kg/dose PO every 24 h, not to exceed 24 mg 0.15 mg/kg (not to exceed 8 mg/dose) IV every 8 h; no single dose should exceed 16 mg due to risk of QT prolongation	First-line therapy for prophylaxis of high-, moderate-, or low-risk CINV or breakthrough CINV	May cause constipation and/or headache; available as an oral disintegrating tablet (that contains phenylalanine) or may be extemporaneously prepared For patients with electrolyte abnormalities, congestive heart failure, bradyarrhythmias, or patients taking other medications with the potential to cause QT prolongation, consider ECG monitoring
Granisetron	<50 kg: 20 μg/kg IV/PO daily; maximum dose 1 mg ≥50 kg: 1 mg IV/PO daily	First-line prophylaxis for high-, moderate-, or low-risk CINV or breakthrough CINV	Available as an oral solution For patients with electrolyte abnormalities, congestive heart failure, bradyarrhythmias, or patients taking other medications with the potential to cause QT prolongation, consider ECG monitoring
Dolasetron	≥2 yr: 1.8 mg/kg IV or PO as a single dose; maximum single dose 100 mg		May be extemporaneously prepared For patients with electrolyte abnormalities, congestive heart failure, bradyarrhythmias, or patients taking other medications with the potential to cause QT prolongation, consider ECG monitoring
Dopamine Antagonist			
Metoclopramide	0.5 mg/kg IV or PO daily (for prophylaxis) 0.5 mg/kg IV or PO every 6 h (for breakthrough CINV) 1 mg/kg IV or PO every 6 h (for severe breakthrough CINV or if lower dose is ineffective)	High-risk prophylaxis; breakthrough CINV	High-dose metoclopramide: Prescribe with diphenhydramine and continue diphenhydramine for 24 h after the last dose to prevent EPS; if the metoclopramide dose is ≤1 mg/kg and the patient weighs >40 kg, scopolamine may be considered Treat EPS with diphenhydramine or benztropine
Corticosteroid			
Dexamethasone	≤BSA 1 m^2: 10 mg/m^2 IV or PO daily BSA >1 m^2: 10-12 mg IV or PO daily; may use 20 mg as a single dose on day 1	High-risk prophylaxis for acute or delayed CINV; breakthrough CINV	Contraindicated in patients receiving pulmonary radiation therapy Consider lower dose if given with an NK-1 receptor antagonist
NK1 Antagonist			
Aprepitant	≥45kg: 125 mg PO ×1 on day 1, then 80 mg PO daily on days 2 and 3	Prophylaxis of acute or delayed CINV	Limited data in pediatrics CYP3A4 substrate and inhibitor of metabolism of drugs that are CYP3A4 substrates including chemotherapeutic drugs (such as vincristine, irinotecan, imatinib, among others) and nonchemotherapeutic drugs (e.g., corticosteroids)
Anticholinergic			
Scopolamine	1.5-mg patch applied transdermally; change every 72 h	High-risk prophylaxis; breakthrough CINV	Use only if >40 kg (the patch cannot be cut); may cause dry mouth and/or blurred vision
Cannabinoid			
Dronabinol	2.5-5 mg/m^2/dose PO every 6 h (10 mg/dose maximum)	High-risk prophylaxis; breakthrough CINV	Do not use in children <6 yr; use with caution if 6-12 yr; may cause confusion, ataxia, hallucinations; no IV form
Anxiolytic			
Lorazepam	<20 kg: 0.025 mg/kg IV or PO every 6 h 20-40 kg: 0.0125 mg/kg IV or PO every 6 h >40 kg: 0.5-2 mg IV or PO every 6 h	High-risk prophylaxis; breakthrough; anticipatory CINV	May cause confusion, sedation, hallucinations, or memory impairment; avoid use of dose greater than 0.5 mg unless proven tolerance of 0.5 mg

BSA, Body surface area; *CINV*, chemotherapy-induced nausea and vomiting; *ECG*, electrocardiogram; *EPS*, extrapyramidal side effects; *IV*, intravenous; *NK1*, neurokinin 1; *PO*, by mouth.

adults may involve formulations of medications that cannot be adjusted for pediatric patients (e.g., capsules or patches). Use of medications in children that are only available in tablet or capsule form also may not be feasible for developmental or psychological reasons.

Dopamine Receptor Antagonists

Dopamine receptor antagonists include the butyrophenones (e.g., droperidol), phenothiazines (e.g., prochlorperazine), and substituted benzamides (e.g., metoclopramide; refer to the "Metoclopramide" section later in this chapter). Until the advent of 5-HT3 receptor antagonists and other antiemetics in the 1990s, dopamine-blocking agents were widely used. Use and efficacy of these agents are limited by their adverse effects, which include sedation and extrapyramidal symptoms (EPS). Children may be at higher risk for EPS, although EPS can often be prevented by concomitant administration of an anticholinergic agent such as diphenhydramine. Scopolamine, an antiemetic in its own right, is sometimes also used for this purpose. We have experience using scopolamine for EPS prophylaxis when the metoclopramide dose is less than or equal to 1 mg/kg/day and the patient weighs 40 kg or more.

Metopimazine, a phenothiazine derivative, is used as an adjunct to 5-HT3 antagonists to treat CINV. Although it is not marketed in North America, metopimazine is used for children in Europe, and a recent small study demonstrated improved emetic control when it was combined with ondansetron compared with ondansetron monotherapy. Olanzapine, an atypical antipsychotic agent, has fewer extrapyramidal effects than do older agents. In small studies in which it is combined with other antiemetics for CINV prophylaxis, olanzapine showed promise in preventing or treating CINV.[248] Chlorpromazine and droperidol both may cause prolongation of the QT interval, and droperidol has been associated with serious cardiac adverse events. Extreme caution, including electrocardiogram monitoring, should be exercised if these agents are used, particularly in patients at risk for arrhythmias. Today use of droperidol is usually limited to the operative period in patients who do not respond to other agents.

5-HT3 Receptor Antagonists

5-HT3 receptor antagonists became the mainstay of therapy in the prevention and treatment of acute CINV since their introduction in the 1990s, when they were shown to be superior to the majority of preexisting antiemetics such as prochlorperazine[249] and metoclopramide,[250-255] even when highly emetogenic chemotherapy such as cisplatin is administered.[251-253]

Compared with other agents, the superiority of 5-HT3 receptor antagonists in preventing acute CINV in children has also been confirmed.[256-260] The efficacy of these agents appears to be further enhanced by the addition of a corticosteroid.[261-263] In one study of 33 children, ondansetron plus dexamethasone provided a complete response in 61% of patients, whereas ondansetron alone provided a complete response in only 21% of patients.[262] Ondansetron has also been shown to reduce acute CINV compared with placebo when chemotherapy is delivered intrathecally.[264]

First-generation agents in this class include ondansetron, dolasetron, and granisetron. Taken together, the data on these agents indicate that these agents are equally effective when given at equivalent doses.[265-271,272] These agents also appear to be equivalent in children, including in situations involving high-dose therapy such as preparative regimens for hematopoietic stem cell transplant.[273-275] In one small study it was found that, compared with tropisetron, ondansetron better controlled acute CINV resulting from use of moderately emetogenic agents. However, no difference was found between the two agents with regard to controlling acute CINV resulting from use of highly emetogenic agents.

5-HT3 antagonists are quite well tolerated by children,[263] with the most common adverse effects reported being mild headache and constipation.[264] 5-HT3 inhibitors, in conjunction with a corticosteroid, are now recommended as first-line therapy for children who receive moderately to highly emetogenic chemotherapy.[246,276]

Efficacy and tolerability of daily administration of high-dose ondansetron (24 mg or 32 mg by mouth daily) has been compared with a smaller dose (8 mg by mouth) given twice daily in adults. A large dose given daily is well tolerated in adults.[277] In a large multicenter, randomized trial, the 24-mg daily dose provided the highest complete control of nausea and vomiting.[278] The superiority of more intensive dosing has been confirmed by other investigators.[279-282] The efficacy of 32 mg compared with 24 mg has also been confirmed by Tsavaris.[283] However, because of the risk for QT interval prolongation in the IV formulation, the 32-mg IV dose is no longer available, and single (daily) doses exceeding 24 mg are not recommended.

Oral and IV routes of administration have been shown to be equally effective in both adults and children.[284-287] Ondansetron, dolasetron, and granisetron are all available in IV formulations and as an oral tablet. Ondansetron is available as an oral dissolving tablet and as an oral liquid; these two preparations are especially attractive in the pediatric population. Granisetron may be extemporaneously compounded by an apothecary. Successful administration of 16 mg of ondansetron daily as a suppository has been described in adults[288] but not in children.

A second-generation 5-HT3 receptor antagonist, palonosetron, differs from its predecessors in its stronger affinity for the 5-HT3 receptor and its prolonged plasma half-life (four times that of the other 5-HT3 antagonists), qualities that may enhance its duration of action.[289,290] In randomized trials in adults, single doses of palonosetron appear to be at least as good in the prevention of acute CINV as single doses of first-generation antagonists delivered 30 minutes before administration of moderately emetogenic chemotherapy. Furthermore, the single dose of long-lasting palonosetron provides better protection from delayed CINV.[291-293] Because of these findings, palonosetron is recommended rather than first-generation 5-HT3 receptor antagonists for adults receiving highly or moderately emetogenic chemotherapy.[294] In pediatric patients palonosetron may prove to be a useful agent in the prevention of acute CINV during multiple-day therapy (in which acute CINV is repeatedly induced) and for the prevention of delayed CINV. Although administration of palonosetron for the prevention of CINV in children has been described,[295,296] further study of dosing, safety, and efficacy is needed before palonosetron can be recommended for children.

Corticosteroids

Corticosteroids are frequently used as antiemetics, although their mechanism of action is unclear. Dexamethasone is the best-studied corticosteroid and the primary one in use today, although success with methylprednisolone has been described. The typical dexamethasone dose used for adults is 10 to 20 mg per day. Our starting dose for children is 10 mg/m^2, to a maximum of 10 mg/day. For persistent vomiting, this dose may be doubled to a maximum of 10 mg given twice a day. If administered with an NK1 receptor antagonist, the corticosteroid dose should be halved.

Dexamethasone provides moderate protection from CINV, including delayed CINV, when used alone.[297-299] Dexamethasone has been shown to be as effective as metoclopramide for acute CINV in adults receiving moderately and highly emetogenic chemotherapy without the extrapyramidal effects of metoclopramide.[300,301]

Dexamethasone is especially useful in preventing delayed CINV from cisplatin, cyclophosphamide, and doxorubicin[302-307] and may be even more effective for this purpose when combined with metoclopramide.[209] Dexamethasone is also very effective in potentiating the action of other antiemetics, including 5-HT3 inhibitors[308] and metoclopramide.[304,306,307,309-312]

In the pediatric population, dexamethasone combined with ondansetron provided significantly more protection from acute CINV that occurred as a result of highly emetogenic agents than did ondansetron monotherapy; 77% of children receiving ondansetron monotherapy had at least one episode of vomiting, compared with 39% who received ondansetron with dexamethasone.[262]

The benefit of improved protection from CINV must be weighed against the risks of corticosteroids. Adverse effects of corticosteroids include metabolic effects, gastritis, insomnia, hypertension, immune dysregulation, impaired wound healing, and adverse psychiatric effects such as emotional lability and, more rarely, psychosis. In general, short courses of corticosteroids do not usually produce significant adverse effects and are often very well accepted and tolerated by patients.[297] Potential beneficial effects of corticosteroids are preservation of appetite and promotion of energy.

Other potential risks include a decrease in action of a biologic response modifier or induction of radiation pneumonitis when a steroid is withdrawn from patients who have undergone lung radiation.[313,314] Caution is advised if corticosteroids are used as antiemetics in conjunction with a treatment regimen that is associated with a high risk of infection or GI toxicity such as induction regimens for acute myelogenous leukemia. Concomitantly administered corticosteroids may further increase these risks. Concerns about the impact of steroids on the blood-brain barrier have led to a desire to avoid the use of steroids as an antiemetic in patients with brain tumors, although chemotherapy-specific data are lacking.[315] The use of steroids may be prohibited when they are already part of a patient's chemotherapeutic regimen.

Metoclopramide

Metoclopramide, a procainamide derivative, exerts antiemetic effects via both a central mechanism (dopamine receptor blockade in the CTZ) and a peripheral mechanism (promotion of gastric emptying).[316] It has been recognized as an effective antiemetic for adults for the past two decades[317] as monotherapy or in conjunction with dexamethasone,[318] lorazepam,[319] or both.[320] Low-dose metoclopramide (i.e., 0.1 mg/kg/dose) is effective in treating postoperative nausea and in promoting gastric emptying.

At high doses, metoclopramide also serves as a serotonin receptor antagonist[191,192] and provides better protection from CINV.[247] For these reasons, metoclopramide is usually given at high doses for CINV. At such higher doses, however, patients—and, in particular, children—are at a greater risk for extrapyramidal adverse effects such as dystonia and akathisia. In a dose-related toxicity study in children, significant extrapyramidal toxicity was observed at doses of 2 mg/kg or higher,[321] and for this reason, high-dose metoclopramide is given with diphenhydramine to decrease the risk of extrapyramidal adverse effects.[247] Extrapyramidal adverse effects can occur up to 24 hours later in patients who receive multiple daily doses of metoclopramide, and thus diphenhydramine administration should continue until 24 hours after the last dose of metoclopramide. We have also had personal experience using transdermal scopolamine as an anticholinergic agent in patients receiving no more than 1 mg/kg/day of metoclopramide. Because of the association of tardive dyskinesia with high-dose or long-term administration of metoclopramide, the FDA issued a boxed warning about this risk in 2009.

Cannabinoids

Delta-9-tetrahydrocannabinol (THC) is the active ingredient in cannabis, or marijuana. THC was approved by the FDA in 1985 for the treatment of emesis. Synthetic THC, called dronabinol (Marinol), has since become available. It is formulated in sesame oil and is available as 2.5- or 5-mg gelatin capsules. A homologue of THC, nabilone, is also now available in the United States.

THC binds to the CB1 receptor found in the central and peripheral nervous systems, as well as the CB2 receptor, which is found in nonneural tissues. THC exerts its antiemetic effect as a receptor agonist, in contrast to other antiemetics, which typically serve as receptor antagonists. THC also interacts with dopaminergic, serotonin, monoaminergic, noradrenergic, and opioid systems, which are pathways that mediate both emesis and pain.

Sallan and colleagues[321a] demonstrated that in patients who have CINV that is not controlled by standard antiemetic therapy, THC provided better complete protection from CINV (in 36 of 79 subjects) than did prochlorperazine (in 16 of 78 subjects). Interestingly, patients younger than 20 years had a higher proportion of complete responses than did older patients. Persons in the THC group also had significantly higher food intake. Adverse effects from cannabinoid administration include sedation, mood alterations (such as euphoria and dysphoria), dizziness, hallucinations, and arterial hypotension. Because of these potential adverse effects, cannabinoids are not typically considered first-line agents for CINV prophylaxis but are added to a regimen if first-line agents are not adequate for prophylaxis or breakthrough CINV.

An advantage of cannabinoids is their utility in treating pain. They are known to bind to kappa and delta receptors and act synergistically with opioids, a feature that may be useful when treating children with both nausea and pain.[322] In addition, they are frequently used to stimulate appetite in patients who are not experiencing nausea or vomiting per se.

NK1 Receptor Antagonists

Aprepitant and its prodrug, fosaprepitant, are the only approved NK1 receptor antagonists. NK1 receptor antagonists are particularly effective in preventing delayed CINV, a historically difficult symptom to prevent. A study was performed to compae cisplatin-naive patients who received granisetron plus dexamethasone on day 1 and either (1) aprepitant (then called L-754,030) on day 1 or (2) aprepitant on days 1 through 5 or (3) placebo on days 1 through 5. In the aprepitant arms, 93% and 94% of subjects had no acute vomiting, compared with 67% in the placebo arm who had no vomiting. Subjects in the aprepitant arms also experienced significantly better complete protection from delayed vomiting (82% and 78%) compared with subjects who received a placebo (33%). In addition, minimal or no nausea was noted in 49% and 48% of subjects in the aprepitant arms and in 25% of subjects who received a placebo.[323]

Other studies have replicated these impressive findings in terms of control of delayed CINV, but they have not demonstrated the improved protection from acute CINV seen in the aforementioned study.[324,325] For example, in a double-blind multicenter trial of 351 patients, aprepitant with dexamethasone provided no benefit in preventing acute emesis when compared with the combination of granisetron and dexamethasone; however, the addition of aprepitant to granisetron and dexamethasone more than doubled the efficacy of this regimen in preventing delayed vomiting.[324]

Aprepitant is generally very well tolerated by adults and adolescents and is easily administered by mouth daily. In addition, it appears to decrease delayed cisplatin-induced CINV that has been established to be refractory to the combination of 5-HT3 antagonists and dexamethasone.[326] The efficacy of aprepitant appears to be sustained over multiple cycles of chemotherapy.[326,327]

Aprepitant is usually administered for 3 consecutive days, because administration on additional days has not been shown to provide better protection from CINV. A pilot study comparing 1-day versus 3-day administration of aprepitant in the prevention of acute and delayed CINV in patients who were receiving highly emetogenic chemotherapy demonstrated no significant difference between the regimens.[328] Additional studies are needed to confirm the noninferiority of the single-day aprepitant regimen.

Studies of the efficacy and safety of aprepitant in children are rare and quite limited methodologically. Use of aprepitant in children as young as 11 years using adult dosing (125 mg on day 1 and 80 mg daily on days 2 and 4) has been reported.[329-331] In the only published prospective trial of aprepitant in children, 46 children aged 11 to 19 years who received emetogenic chemotherapy along with ondansetron and dexamethasone for 4 days were randomly assigned to also receive aprepitant or placebo for 3 days. In this study, which was designed to evaluate pharmacokinetics and tolerability, it was found that aprepitant was well tolerated but that febrile neutropenia occurred more often in children who received aprepitant, although the overall infection rate was higher in the placebo group. The limited sample size may have contributed to these findings and prevented statistical significance in the assessment of efficacy. The study demonstrated that pharmacokinetics in adolescents is similar to that of adults, and it is therefore reasonable to administer the adult dose to this age group.[331] Administration of a lower dose (80 mg/day for 3 days) to smaller children (<20 kg) has been described, but the efficacy of this regimen in preventing CINV was not reported.[330]

Fosaprepitant is an IV prodrug of aprepitant that is approved for administration in adults as a one-time dose prior to the administration of chemotherapy. Administration of this one-time dose given with ondansetron and dexamethasone provides protection from acute and delayed CINV that is equivalent to a regimen of aprepitant, ondansetron, and dexamethasone.[332] Fosaprepitant dosing in children is currently being studied.

Aprepitant is a CYP3A4 enzyme pathway substrate and inhibitor and therefore may alter levels of drugs metabolized via this pathway. Concomitant administration with aprepitant may raise the level of drugs such as dexamethasone, methylprednisolone, fentanyl, cyclophosphamide, thiotepa, vincristine, or etoposide.[333,334] For this reason aprepitant should be prescribed with care to avoid potential interactions, and the patient should be monitored closely for such interactions. It has been suggested that when aprepitant is coadministered with dexamethasone for CINV prophylaxis, the dexamethasone dose should be decreased by 50%.[335] Aprepitant does not appear to alter the pharmacokinetics of ondansetron or granisetron.[336] Aprepitant should be used with caution in patients who take warfarin.[337]

Other Agents

Lorazepam is often used as an adjuvant to true antiemetics because of its anxiolytic and amnestic properties. Early studies evaluating the addition of lorazepam found that patients reported less anxiety and preferred regimens that contained this additional agent, although it did cause more sedation.[338-340] The acute antiemetic effect of several agents is enhanced when lorazepam is given concomitantly.[341-343] Interestingly, the addition of lorazepam to regimens that contained dexamethasone as prophylaxis against delayed CINV from cisplatin appears to decrease delayed CINV as well.[303,341]

Scopolamine is a muscarinic antagonist that is known to reduce motion sickness. It is inadequate as monotherapy for CINV,[344] but in conjunction with other antiemetics such as metoclopramide and dexamethasone, it reduces cisplatin-induced CINV.[345] Scopolamine is administered as a 1.5-mg transdermal patch applied behind the ear that releases 0.5 mg/day and must be changed every 3 days. Because the patch is only available in the 1.5-mg size and cannot be cut, we normally reserve it for children who weigh 40 kg or more. Adverse effects from scopolamine include dry mouth, blurry vision, and mydriasis from systemic effects. Mydriasis on the side ipsilateral to the patch from unintentional touching of the patch followed by rubbing of the eyes can also occur.[346]

Antihistamines such as dimenhydramine, hydroxyzine, and diphenhydramine are effective in reducing the nausea associated with vertigo and motion sickness. For CINV management, diphenhydramine is often given in regimens containing high-dose metoclopramide to prevent extrapyramidal effects. Diphenhydramine does not, however, enhance the antiemetic effect of metoclopramide,[347,348] and apart from preventing extrapyramidal effects, it should not be used for CINV management.

Olanzapine is an atypical antipsychotic agent that binds to several receptors, including dopamine, serotonin, and to a lesser extent histamine and muscarinic receptors. Because of its action at multiple receptor sites implicated in CINV, it may hold promise as a therapy for CINV. In a small study of 10 adult patients receiving moderately to highly emetogenic chemotherapy with olanzapine, palonosetron, and dexamethasone as antiemetic prophylaxis, 100% had complete protection from nausea and vomiting in the first 24 hours after chemotherapy, with 50% and 75% of patients protected from nausea and vomiting, respectively, on days 2 to 5.[349] Olanzapine is consequently included in some guidelines for adults with CINV. No studies evaluating olanzapine for children with CINV have been published.

Gabapentin has also been evaluated for CINV in adults.[350] One study showed a decrease in peak nausea scores for both acute and delayed CINV, indicating that this agent may also hold promise as a therapy for CINV.

Special Cases

Delayed Vomiting. Until very recent years, steroids and metoclopramide were the primary agents used to control delayed vomiting,[209,305,320] with modest protection from delayed CINV in 48% to 57% of adult patients. Some studies have demonstrated efficacy of 5-HT3 antagonists in preventing delayed CINV[351,352] and providing better protection when compared with existing drugs such as prochlorperazine.[353] However, the majority of studies have demonstrated that the addition of a 5-HT3 receptor antagonist to the standard therapy, dexamethasone, does not confer greater protection from delayed CINV.[211,212,354-357] In a meta-analysis of the efficacy of 5-HT3 antagonists, these antagonists did not confer protection from delayed CINV significantly beyond that provided by dexamethasone monotherapy. When ondansetron plus dexamethasone was compared with metoclopramide plus dexamethasone in randomized controlled trials, 5-HT3 was equivocal at best.[358-360]

In one pediatric study evaluating ondansetron for acute and delayed CINV after treatment with carboplatin, cisplatin, Adriamycin with cyclophosphamide, or ifosfamide, ondansetron prevented acute CINV in 87% of children. Its efficacy in preventing delayed CINV was not nearly as high; it prevented only 20% of children from experiencing nausea and 50% of children from vomiting after administration of cisplatin or ifosfamide. A reasonable approach would be to start with dexamethasone and metoclopramide. In children who do not tolerate or who do not respond to metoclopramide, a 5-HT3 antagonist such as ondansetron may then be tried as an alternative.

In adults, some of the best protection from delayed CINV is conferred by the combination of a single dose of palonosetron with three doses of aprepitant and concurrent dexamethasone. In one study, this regimen provided a complete response (no emesis and no rescue medication) for 88% of patients in the acute period and 78% during the delayed period.[361] Evidence for the efficacy of palonosetron in preventing delayed CINV is limited to single-day administration regimens. Interest in consecutive daily dosing of palonosetron to cover multiday chemotherapy has been expressed. Multiple dosing of palonosetron has recently been approved for adults.

Numerous studies in adults have demonstrated the effectiveness of aprepitant for delayed CINV, as previously described. Because most studies of aprepitant have been in the setting of single-day emetogenic treatment, it can be difficult to know how best to utilize this drug in the setting of the multiday regimens common in pediatrics. It is our practice to give the drug for up to 5 days, which may or may not continue beyond the end of the emetogenic treatment.

Anticipatory Nausea. Because anticipatory CINV it is a learned response, typical antiemetics are generally ineffective. The best strategy for preventing CINV is the prevention of CINV in previous courses of chemotherapy.[213] Because anxiety plays a key role in anticipatory nausea, use of an anxiolytic such as lorazepam may be effective.

Breakthrough Emesis. Breakthrough emesis is defined as vomiting that occurs in spite of optimal preventive therapy. Although no studies of breakthrough emesis have been performed and no widely accepted standards are available, a reasonable approach is (1) ensuring that the patient is receiving maximal doses of current antiemetics and (2) adding a rescue agent from a category different from those the patient is already receiving. Although breakthrough agents may be started on an as-needed basis, scheduled administration may be needed during the current or future cycles.

Radiation-Induced Nausea and Vomiting

Radiation-induced nausea and vomiting occurs acutely in more than 90% of adult patients who receive total body

TABLE 71-4 Emetogenicity of Chemotherapeutic Agents and Radiotherapy Fields Commonly Used in Pediatrics

	RISK OF EMESIS			
Modality	**High (>90%)**	**Moderate (30%-90%)**	**Low (10%-30%)**	**Minimal (<10%)**
Chemotherapy	Carmustine (BCNU) Cisplatin Cyclophosphamide (>1500 mg/m^2) Dacarbazine (DTIC) Dactinomycin Ifosfamide (≥500 mg/m^2) Lomustine (CCNU) Mechlorethamine (nitrogen mustard) Procarbazine Thiotepa (≥300 mg/m^2)	Arsenic trioxide Carboplatin Clofarabine Cyclophosphamide (750-1500 mg/m^2) Cytarabine (>1000 mg/m^2) Cytarabine (intrathecal) Daunorubicin Doxorubicin Epirubicin Idarubicin Ifosfamide (<500 mg/m^2) Irinotecan Melphalan (>50 mg/m^2) Methotrexate (>1000 mg/m^2)	Cyclophosphamide (≤750 mg/m^2) Cytarabine (<1000 mg/m^2) Etoposide (VP-16) 5-Fluorouracil Gemcitabine Imatinib Methotrexate (50-1000 mg/m^2) Mitomycin Mitoxantrone Topotecan Vinblastine Vorinostat	2-Chloroxydeadenosine (cladribine) Asparaginase Bortezomib Bleomycin Busulfan Decitabine Fludarabine Hydroxyurea Mercaptopurine Methotrexate (<50 mg/m^2) Monoclonal antibodies (e.g., rituximab) Thioguanine Vincristine Vinorelbine
Radiotherapy	Total-body irradiation Upper abdomen (moderate to high risk)	Abdominal-pelvic Craniospinal Hemibody irradiation	Cranium Lower thorax Mantle	Other (e.g., extremity)

irradiation for bone marrow transplantation and within 30 to 60 minutes in 80% of adults who receive single high-dose/large-field hemibody irradiation. Radiation-induced nausea and vomiting may also occur within 2 to 3 weeks in about 50% of adults who receive fractionated radiotherapy to the abdomen.[362] The incidence and severity of radiotherapy-induced nausea and vomiting is largely related to the location of the radiation field, as indicated in Table 71-4. In a prospective study of adults undergoing radiotherapy, the two radiotherapy-related risk factors for nausea and vomiting were the site of irradiation and the field size, with significantly more vomiting in persons who received radiation to the upper abdomen and in those with a radiation field size greater than 400 cm^2.[363] The only patient-related factor was previous experience with cancer chemotherapy. Because radiation to the upper/mid hemibody results in an increase in circulating serotonin metabolites and because of the efficacy of 5HT-3 receptor antagonists in this setting, it has been proposed that serotonin mediates radiation-induced emesis.[364]

In patients receiving single-dose radiation to the upper abdomen, ondansetron has been demonstrated to be superior to metoclopramide in reducing vomiting and nausea.[365] In a randomized controlled trial comparing ondansetron with prochlorperazine in adults receiving fractionated radiotherapy to the abdomen, 43 (61%) of patients in the ondansetron arm and 23 (35%) of patients in the prochlorperazine arm had a complete response, that is, complete protection from emesis throughout their entire treatment course (P = .002). However, no difference was found in the incidence or severity of nausea in the two groups.[366] Although no controlled trials have been performed in the pediatric population, studies have demonstrated its efficacy and tolerability during radiotherapy.[367] Dolasetron has also been used successfully to prevent nausea after a single high-dose fraction of radiotherapy to the upper abdomen.[368]

The addition of dexamethasone to ondansetron appears to confer a slight benefit to ondansetron, even for multiply fractionated radiation to the upper abdomen.[369] Current adult guidelines recommend prophylaxis with a 5-HT3 receptor antagonist before each fraction and for 24 hours after the last fraction for patients at high or moderate risk of radiation-induced vomiting (i.e., total body irradiation and radiation directed at the upper abdomen); prophylaxis or rescue with a 5-HT3 receptor antagonist in the low-risk group (i.e., those with radiation directed at the lower thorax, pelvis, or cranium); and rescue with a dopamine or 5-HT3 antagonist in the minimal risk group (i.e., patients with radiation directed at the head and neck, extremities, and breast).[370] One study evaluating ondansetron in children undergoing radiotherapy has been performed.[367] In this study it was found that ondansetron provided 60% protection in children undergoing radiation therapy for a brain tumor, although no control subjects were used for comparison.

Postoperative Vomiting

Postoperative nausea and vomiting (PONV) is a common problem in all pediatric patients. Recent studies have demonstrated that dexamethasone is effective in preventing acute and late PONV.[371-373] Droperidol is also an effective agent, but given the high level of sedation, risk of EPS, and the recent concern of cardiotoxicity, this agent is no longer considered first-line prophylaxis.[374] A significant number of studies have evaluated the efficacy of ondansetron in preventing PONV in children, and this agent is considered the drug of choice for this situation.[374,375] Pooled analyses, however, show that the efficacy lies primarily in an antiemetic effect rather than an antinausea effect.[375]

A recent controlled study of adults undergoing surgery also showed that scopolamine may be a promising agent in preventing PONV in adults, although it caused the symptom of dry mouth to a considerable degree.[376] Two large adult studies have recently shown that one dose of aprepitant is superior to ondansetron in preventing postoperative vomiting; however, only one study found a significant reduction in postoperative nausea.[377,378]

Vomiting from Other Causes

Opioid-Induced Nausea and Vomiting

Although reactions to opioids are frequently, and incorrectly, labeled as an allergy, they can cause nausea and vomiting. Such effects are mediated through (1) direct effects of opioids on the CTZ, (2) effects on the vestibular apparatus, and (3) signals from the gut as a result of constipation. Except when it is due to constipation, opioid-related nausea and vomiting tends to improve with repeated dosing of the opioid. Therefore a reasonable strategy is to provide an antiemetic with the first few doses of the opioid, particularly if the patient is at risk for nausea and vomiting. This strategy prevents the problem of the patient being labeled as "allergic" to the opioid.

Although no evidence is available to indicate that one opioid is more emetogenic than another, it is commonly believed that morphine and codeine are the most likely opioids to cause nausea and vomiting. If nausea and vomiting in response to an opioid persist despite use of antiemetics, it may be reasonable to consider changing the opioid or route of administration. Because tolerance to the emetogenic effect of the initial opioid usually develops in a few days, however, it may be difficult to know whether it was tolerance or the change in opioid that improved symptoms.

Data comparing antiemetics for opioid-induced nausea and vomiting are limited. One study compared 24 mg of daily ondansetron with either metoclopramide, 10 mg by mouth three times a day, or placebo. No differences were detected in the three arms, although the study was terminated prematurely as a result of accrual difficulties.[379] In another study of adults receiving opioids for postsurgical pain, single doses of either 8 or 16 mg of ondansetron provided better emetic control than did a single 10-mg dose of metoclopramide. One report also indicates that ondansetron may be effective in preventing nausea and vomiting from morphine administered via the spine.[380] Recent publications have also demonstrated that the addition of a low-dose naloxone infusion may reduce opioid-related adverse effects, including nausea, without affecting analgesia in both adults and children.[381-383]

Disease-Related Vomiting

Outside of direct treatment-related nausea and vomiting, disease processes themselves may cause nausea and vomiting through a variety of mechanisms, including increased intracranial pressure, GI obstruction, altered gut motility, organ capsule distension, or GVHD. For example, altered gut motility appears to contribute to nausea and vomiting in patients recovering from bone marrow transplantation.[384-386] Interestingly, recent reports have indicated that mirtazapine, a new serotonin-norepinephrine reuptake inhibitor, improves nausea and vomiting in patients with gastroparesis from a variety of causes, but mirtazapine has not been studied for this purpose in patients undergoing bone marrow transplantation or in children.[387-390]

In addition, other processes that may or may not be related to the disease process or its treatment, such as GI infection, may be present. The mnemonic V.O.M.I.T. may be used to review the possible underlying causes of nausea and vomiting so that a targeted approach to the situation may be undertaken.[391] This mnemonic indicates that nausea and vomiting may be due to **v**estibular problems, **o**bstruction of the bowel (including constipation), gut dys**m**otility, **i**nfection and inflammation, and **t**oxins. Remarkably little is known about the effectiveness of antiemetics for these causes, and treatment of the underlying problem may be the best strategy. Ondansetron has a modest effect in controlling vomiting that occurs as a result of acute gastroenteritis.[392]

Nonpharmacologic Interventions

Acupuncture and behavioral therapies are some of the best-studied nonpharmacologic interventions for CINV. Electroacupuncture reduced vomiting but not nausea in women undergoing myeloablative chemotherapy when compared with control subjects.[393] In children, P6 acupoint injections are as effective as droperidol in preventing postoperative nausea and vomiting.[394]

Acupressure and acustimulation have also been studied as interventions to mitigate CINV. In one relatively large study of 739 patients who were randomly assigned to use an acupressure band, an acustimulation band, or no band, persons who received acupressure bands had less nausea on the day of treatment, but no differences in delayed nausea were found.[395] In pooled analyses of trials evaluating acupuncture-point stimulation, these interventions reduced the proportion of acute vomiting but not the severity of nausea. When broken down by modality, stimulation with needles and electroacupuncture reduced vomiting but not nausea. Acupressure reduced nausea but not vomiting, but these studies were not controlled.[396]

In children receiving chemotherapy, behavioral interventions such as hypnosis and cognitive distraction reduce nausea, vomiting, and the extent to which these symptoms bothered the children, and these effects were maintained even after the interventions were discontinued and chemotherapy was continued.[239] Behavioral interventions such as hypnosis and systemic desensitization also appear to be useful in treating anticipatory nausea, a phenomenon with a strong learned component.[397,398] Progressive muscle relaxation has been shown to reduce the duration of CINV in women with breast cancer but not the intensity or frequency of nausea or vomiting episodes.[399]

Role of the Patient and Family

Because patients who anticipate CINV may be more likely to actually experience it, discussing the role of interventions to prevent or mitigate CINV may enhance the efficacy of these interventions. Patients and families should also be encouraged to record their symptoms in a diary and to notify their medical team of uncontrolled symptoms when they occur, particularly because uncontrolled acute nausea is associated with increased incidence of both delayed nausea and anticipatory nausea with future chemotherapy. The phenomenon of delayed nausea should specifically be addressed, because children and their parents are usually at home and unable to be observed at the time the child may experience these symptoms.

Strategies to enhance patients' sense of control over their treatment may also improve their experience. In one small study of adults with CINV that was controlled with IV antiemetics via a pump, the patients who were able to control the pump themselves used less antiemetic.[400] More recent studies in both adults and children indicate that a continuous infusion, patient-controlled pump is well tolerated, safe, and effective in controlling CINV.[401,402] Patients should be encouraged to explore strategies for nonpharmacologic management if these options are of interest, because they appear to have little downside and can also add to the patient's sense of control over his or her experience.

Future Directions

Significant advances have been made in the past few decades with regard to managing nausea and vomiting, particularly CINV; however, more remains to be done to improve the management of these symptoms in children. More knowledge is needed regarding assessment of the symptom of nausea, looking beyond the quantification of vomiting, along with the determination of a child's risk for the development of nausea to begin with.

Pharmacogenomics may play a role in finding candidate genes that may predict emetic sensitivity and responsiveness to antiemetic therapy, which may help clinicians identify patients who are unlikely to respond to conventional therapies. Optimal regimens for multiple-day and high-dose chemotherapy or bone marrow transplantation, as well as new strategies for control of delayed and refractory symptoms, are also needed. Exploration of drugs, such as the new atypical antipsychotic medications or new small molecules, may contribute to this area.

For children in particular, more evidence of efficacy and adverse effects are needed, as are evidence-based guidelines for CINV management to address the wide variations in practice that exist. Finally, knowledge of nausea and vomiting in children historically has been based on CINV or postoperative situations. Much remains to be learned regarding non–chemotherapy-related nausea and vomiting.

OTHER GASTROINTESTINAL SYMPTOMS

Constipation

Constipation is the passage of hard feces that typically occurs with difficulty and decreased frequency. Most children who experience constipation have no history of bowel dysfunction prior to their cancer diagnosis. Children who have cancer are predisposed to the development of constipation when compared with healthy children because of their decreased fluid intake, variable diet, and decreased mobility, in addition to specific cancer- and treatment-related causes. Constipation may be caused by direct effects of the cancer such as a tumor that obstructs the intestinal lumen, infiltrates enteric nerves and muscles, or causes spinal cord compression or cauda equina syndrome. Cancer-directed therapy, particularly neurotoxic agents such as vinca alkaloids, may also cause constipation. In addition, use of opioids may be one of the most important causes of constipation in this population.

Constipation may lead to painful bowel movements, which some children respond to by withholding stool, further exacerbating the problem. Constipation may lead to significant distress, discomfort (e.g., pain, nausea, and bloating), and embarrassment for some children. Medical complications may include GI obstruction, urinary obstruction, or infection.

Constipation is usually due to altered GI motility and/or altered fluid handling. Intestinal motility is controlled by neuronal, endocrine, and luminal factors. Acetylcholine is the chief neurotransmitter that mediates peristalsis. Serotonin also plays an important role in mediating the gut's response to luminal contents. Opioids lead to constipation by reducing intestinal motility and secretions and increasing fluid absorption and blood flow,[403] as well as by decreasing sensitivity to luminal contents. The effects of opioids on the gut do not appear to be strongly related to the dose.

Evaluation of the patient with constipation includes a thorough history and physical examination. If not contraindicated by a condition such as neutropenia or mucositis, a rectal examination may facilitate the distinction of lower (rectosigmoid) constipation from "colonic inertia" or high obstruction and may also allow assessment of anal sphincter tone and examination for fissures or hemorrhoids. When the diagnosis of constipation is unclear, a radiograph of the kidneys, ureters, and bladder may facilitate the diagnosis.

In addition to medical interventions, the treatment of constipation includes strategies such as provision of a comfortable, easily accessible toilet or commode and addressing issues such as lack of privacy and the need for care providers to help the patient with toileting. Although physical activity is associated with colonic peristalsis, increasing exercise does not necessarily reduce constipation.[404] In addition, the child's medications should be reviewed and dosing of constipating medications such as opioids, TCAs, antihistamines, and 5-HT3 receptor antagonists such as ondansetron and neuroleptics should be altered, if possible. For example, transdermal fentanyl may be less constipating than oral morphine.[405] Patients taking methadone have less of a laxative requirement than do patients taking morphine or hydromorphone, perhaps because methadone provides analgesia by binding to both opioid and NMDA receptors.[406]

Medical management of constipation relies on stool softeners, osmotic agents, and irritant stimulants that increase bowel motility. Softeners, by acting as detergents, soften the stool. Osmotic agents include lactulose, polyethylene glycol, and magnesium salts and increase secretion of water into the lumen. Osmotic agents that increase stool volume actually also facilitate contraction of the bowel wall musculature, thereby increasing bowel motility. Polyethylene glycol is a tasteless agent that may be mixed with a beverage of the child's choice, making it an attractive option for children. In addition, because it is a large polymer that is not degraded by bacteria, it causes less bloating and flatulence than other osmotic agents.[407]

Irritant stimulants such as senna and bisacodyl stimulate contraction and increase secretion. Both of these agents act quickly and are most appropriately used in single doses for temporary constipation. When a hard, leading edge of stool is detected in the rectal vault on examination, it may need to be addressed with use of rectal laxatives (i.e., stimulant suppositories or enemas) if these are acceptable to the child and are not contraindicated because of neutropenia. In the neutropenic child requiring rectal laxatives, administration of antibiotics may prevent bacterial translocation during these maneuvers. As a last resort, manual disimpaction may be required for impacted, hard stool in the rectal vault. Manual disimpaction is a very uncomfortable and distressing procedure for many children and should be avoided if possible.

Although increased fiber intake may be a useful strategy for reducing constipation in healthy persons, patients with cancer may be unable to consume enough fiber to prevent constipation. Inadequate fluid intake directly contributes to constipation but also reduces the efficacy of fiber and increases the risk of obstruction due to a gelatinous mass from inadequately hydrated fiber.[403]

The most effective approach to predictable constipation due to opioids or vinca alkaloids is prevention. Because constipation is one adverse effect of opioids to which patients do not develop tolerance, opioids should always be prescribed with a bowel regimen including a stool softener and stimulant. Despite wide recognition of the constipating effects of opioids, as many as 26% of health care providers who prescribe opioids fail to provide bowel prophylaxis.[408] Other barriers to effective prevention of constipation include (1) difficulty in convincing patients to take a medication to *prevent* another symptom, (2) multiple daily dosing for softeners and laxatives, and (3) adverse effects from these agents such as abdominal pain, cramping, and loose stools.[403]

Methylnaltrexone, a novel agent that may be given orally, intravenously, or subcutaneously to treat opioid-induced constipation, has recently been evaluated in adults.[409,410] This opioid receptor antagonist binds to peripheral mu opioid receptors and does not cross the blood-brain barrier. As such it does not reverse analgesia or induce withdrawal but reliably results in a prompt bowel movement, often within minutes of parenteral administration. It may provide added benefits of treating other peripheral opioid adverse effects such as nausea, pruritus, and urinary retention. It provides the added benefit of relieving opioid-induced constipation without the addition of an enteral medication. Methylnaltrexone is contraindicated in the setting of mechanical GI obstruction or an acute surgical abdomen. Although a pediatric study is required to determine the optimal pediatric methylnaltrexone dose, in one retrospective study it was found that after administration of methylnaltrexone at a mean dose of 0.15 mg/kg/dose, 10 of 19 patients (53%) had a bowel movement within 30 minutes and an additional 4 patients (for a total of 14/19, or 74%) did so within 4 hours of administration.[383]

Bowel Obstruction

Bowel obstruction may result from tumor (malignant bowel obstruction) or other entities such as strictures or postradiation fibrosis obstructing the intestinal lumen. Factors that reduce bowel propulsion such as electrolyte imbalance, opioids, and vinca alkaloids may also contribute to bowel obstruction. Bowel obstruction may occur anywhere from the gastroduodenal junction distally and typically causes abdominal pain, colic, distension, and nausea and vomiting.

Management options for obstruction depend on the site and the underlying cause of the obstruction, the patient's functional status and prognosis, and the goals of care of the patient and family. Treatment modalities for obstruction include surgery, endoscopic procedures, radiation, and medical interventions. For these reasons, decisions regarding management of obstruction may likely involve an interdisciplinary discussion with the family.

Surgery, either by laparoscopy or laparotomy, is often the primary treatment for a mechanical bowel obstruction. Such techniques may allow for resection or bypass of the obstruction and perhaps placement of a venting gastrostomy or a stoma distally. Obstructions may also sometimes be stented endoscopically. Consultation with a surgeon to determine the likelihood of success of the procedure and the potential for obstruction to recur in light of the patient's medical condition may be helpful. Even if obstruction is likely to recur, for some patients it may be reasonable to consider surgery if it is likely to restore bowel function or reduce symptoms for a period. For example, a relatively minor surgery such as gastrostomy placement may allow for venting of an upper obstruction, reducing nausea and vomiting and allowing the patient to eat for comfort.

For some patients, such as those with advanced disease and poor functional status, medical management may be more appropriate than surgery. A variety of medical interventions may break the cycle of obstruction, distension, and secretion. These interventions are aimed at relieving symptoms and potentially reducing the obstruction to allow some degree of enteral nutrition.

Antimuscarinic/anticholinergic agents such as scopolamine reduce colic from smooth muscle spasm and reduce GI secretions. Scopolamine may be administered intravenously, subcutaneously, or transdermally. Because it crosses the blood-brain barrier, it may cause CNS effects such as delirium; glycopyrrolate, which does not cross the blood-brain barrier, is sometimes used as an alternative.

Octreotide is a somatostatin analogue that is a potent antisecretogogue. By inhibiting several hormones, as well as neurotransmission, in the GI tract, it reduces splanchnic blood flow and peristalsis, reduces gastric and intestinal secretions, and increases the absorption of water and salts from the intestine. Octreotide may be given subcutaneously or intravenously, and a long-acting injection formulation is available for once-monthly dosing for patients taking a stable dose.

In a randomized trial of 68 adults with an inoperable malignant bowel obstruction who were receiving an anticholinergic agent, antiemetics, and an opioid, those who also received octreotide had significantly reduced nausea, vomiting, anorexia, and fatigue, although no difference in pain was appreciated.[411] In an uncontrolled study of 27 adults who had an inoperable malignant bowel obstruction, a combination of octreotide, dexamethasone, metoclopramide, opioids, and other agents produced a 90% recovery rate.[412] This regimen reduced vomiting, restored intestinal motility, and allowed for oral feedings.

Other medications that may be helpful include prokinetic drugs such as metoclopramide, which reverses peristalsis from obstruction and decreases nausea and need not be reserved only for partial obstruction. Other pharmacologic interventions include corticosteroids, which decrease inflammation and edema and reduce nausea. For some patients, a venting gastrostomy tube may reduce symptoms. IV hydration may reduce nausea and sedation.[413] Both surgical approaches and medical hydration/nutrition, however, are supportive measures that should be considered in light of the patient's prognosis and the goals of the patient and family.

Diarrhea

Diarrhea is defined as the frequent occurrence of loose stools, often with urgency. Patients' definitions of diarrhea may vary, and when it is a presenting complaint, it must be accurately characterized, particularly with regard to how the patient's bowel habits have changed compared with his or her baseline. In addition to potentially causing significant medical complications, diarrhea may be debilitating for patients. It may cause life-threatening dehydration and electrolyte imbalance in addition to malnutrition and immune impairment. Attendant mucosal injury may also predispose patients to sepsis. Diarrhea may cause physical discomfort with cramping and painful perianal skin breakdown and emotional distress for children and caregivers.

Diarrhea may occur as a direct effect of a malignancy (e.g., a carcinoid, a GI stromal tumor, or medullary cancer of the thyroid), although this occurrence is relatively rare in pediatric cancers. Secretory diarrhea can occur in rare cases of neuroblastoma with associated vasoactive intestinal polypeptide secretion. Diarrhea may also result from chemotherapy, as will be discussed later. Radiation to the abdomen or pelvis may cause mucosal damage, prostaglandin release, and bile salt malabsorption, which in turn increase peristalsis and cause diarrhea. Radiation-induced enteritis frequently occurs during the third week of fractionated therapy.[414] Another form of treatment-related diarrhea is gut GVHD after bone marrow transplant. In gut GVHD, inflammatory infiltrates of activated lymphocytes, plasma cells, and eosinophils cause intestinal mucosal damage, in turn leading to diarrhea and sometimes bleeding.[415] Mucosal damage from cancer treatment may increase the risk of superinfection, which can further exacerbate diarrhea and other GI symptoms.

Other causes of diarrhea in patients with cancer include bacterial overgrowth, which may occur with changes in anatomy after surgery, as well as bona fide infection. In particular, patients with cancer are prone to *Clostridium difficile* infections largely as a result of the frequent administration of antibiotics. Infection leads to diarrhea through mucosal injury and impaired absorption, although malabsorption may occur for other reasons, such as a surgically shortened gut or fistula that reduces absorptive capacity.

Diarrhea may also be caused by medications, including antibiotics and magnesium (in electrolyte supplements or antacids). Furthermore, diarrhea may be seen in association with constipation, either as a result of impaction constipation with overflow or leakage or laxatives used to treat constipation.

In general, treatment of diarrhea depends on the underlying cause. If needed, rehydration should be undertaken with correction of electrolyte imbalance. Patients should be advised that food intake is secondary to maintenance of hydration during an episode of diarrhea. Dairy products should be avoided because of secondary lactase deficiency. In addition, a topical skin barrier such as Desitin may be applied to protect the skin from irritation. Symptomatic management with opioids, and in the case of severe diarrhea, octreotide, is discussed later in the context of chemotherapy-induced diarrhea (CID), but it is applicable to diarrhea from a wide variety of causes.

Chemotherapy-Induced Diarrhea

CID is seen with increasing frequency as an adverse effect of new chemotherapeutic agents. It is a common adverse effect of agents such as 5-fluorouracil, irinotecan, capecitabine, and docetaxel. Irinotecan may cause acute diarrhea immediately after administration of the drug through cholinergic mechanisms; the diarrhea may be treated with an anticholinergic agent such as atropine. Irinotecan commonly causes delayed diarrhea, usually at least 24 hours after administration. Irinotecan is conjugated by the liver to form SN-38, which is then deconjugated back to the active agent in the intestinal lumen by bacteria. The irinotecan is then able to directly exert toxic effects on colonic epithelium, resulting in diarrhea.[416,417] The late onset secretory diarrhea is best prevented by antibiotics, and if necessary, it is treated with loperamide.

Loperamide is the opioid of choice for diarrhea because it acts locally in the gut and is only very minimally absorbed. By slowing peristalsis and promoting water reabsorption, it reduces stool frequency and volume, as well as urgency. If systemic absorption is less of a concern, other opioids such as morphine may be used as well. Loperamide may be discontinued after the patient has been free of diarrhea for 12 hours, but in the case of radiation-induced diarrhea, loperamide should be continued for the duration of radiation treatment.[414] In cases in which CID is severe or complicated (i.e., with moderate to severe cramping, decreased performance status, fever, neutropenia, and bleeding or dehydration), administration of octreotide should be considered.[414] Octreotide is also effective in cases of diarrhea refractory to loperamide,[418] and it has been shown to be effective in reducing diarrhea associated with GVHD.[419] In a small study of pediatric patients receiving irinotecan, it was found that activated charcoal taken three times a day during irinotecan administration reduced the severity and frequency of diarrhea and improved chemotherapy tolerability and continuation rates.[420]

DYSPNEA

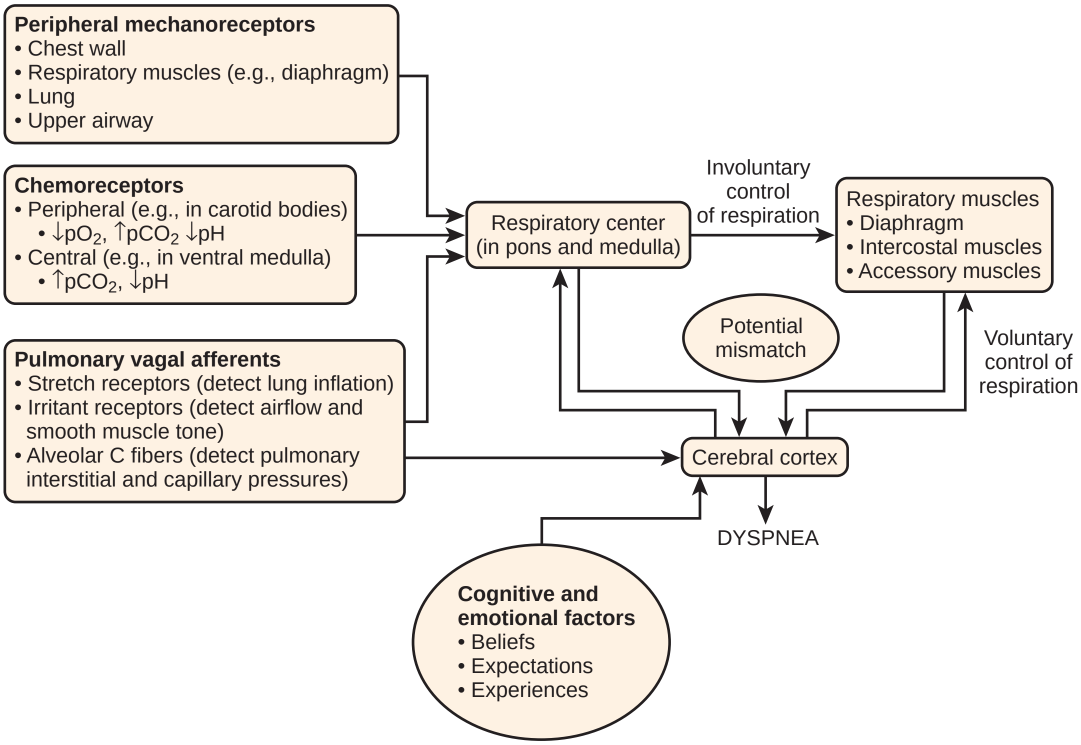
Dyspnea is defined as the uncomfortable or abnormal awareness of breathing. Patients may describe dyspnea in a variety of ways, including chest tightness, air hunger, choking, or heavy breathing. Dyspnea is clearly an important source of suffering in children and adults alike, triggering feelings of fear, anxiety, and loss of control and impairing quality of life.[421] In addition, family members are distressed by witnessing a loved one with this symptom.[422]

Dyspnea may occur in patients with malignant involvement of the respiratory tract. Direct effects of malignancy such as airway obstruction by tumor or a malignant pleural effusion are possible. Treatment-related complications such as pulmonary fibrosis, pneumonitis, or GVHD after hematopoietic stem cell transplantation may cause dyspnea. Other respiratory processes that result in dyspnea include pulmonary edema, pulmonary embolus, pneumonitis, or a restrictive physiology due to tumor, ascites, or organomegaly. Patients with cardiac pathologic conditions such as anthracycline-induced congestive heart failure or pericardial effusion may also experience dyspnea. Despite the multitude of potential causes of dyspnea, it may also occur in patients who have no respiratory or cardiac involvement at all. For example, in the National Hospice Study it was found that 24% of terminally ill adults with cancer who reported dyspnea had no known cardiac or pulmonary disease.[423] In cases in which no known underlying respiratory or cardiac disease exists, dyspnea may stem from multiple causes, including muscle weakness from deconditioning or poor nutritional status, anemia, metabolic derangements, fluid shifts, or anxiety.

Dyspnea may occur at any point during the clinical course but is most notably observed at the end of life. In the National Hospice Study it was found that 70% of 1754 terminally ill adults experienced dyspnea in the last 6 weeks of life.[423] Dyspnea, particularly dyspnea at the severe end of the spectrum, is associated with shorter survival. For example, as a symptom by itself or in association with other parameters, it is a prognostic indicator of more rapid mortality in adults with advanced cancer.[424]

Pathophysiology

The respiratory center that processes input from the respiratory system and coordinates respiratory activity is located in the medulla and pons. Afferent input arises from peripheral mechanoreceptors in respiratory muscles, the chest wall, the lungs, and the upper airway, as well as central and peripheral chemoreceptors and pulmonary vagal afferents (Fig. 71-4). Chemoreceptors detect low P_{O_2} and high P_{CO_2} in the blood and send this input to



Peripheral mechanoreceptors
• Chest wall
• Respiratory muscles (e.g., diaphragm)

the respiratory center. Pulmonary vagal afferents are activated by input from stretch receptors and irritant receptors, and they also trigger activity in tracts that project to the cerebral cortex. Based on this sensory input, the respiratory center coordinates the respiratory apparatus consisting of the diaphragm, intercostal muscles, and accessory muscles. The cerebral cortex integrates sensory input, motor output, and cognitive and emotional input to create the sensation of breathing.[425]

The phenomenon of dyspnea occurs when the afferent sensory input to the brain—for example, input from mechanoreceptors in the chest wall—fails to match the outgoing motor signal emanating from the brain.[426] Situations in which such mismatch may occur include (1) increased work of breathing such as when breathing against increased resistance or with weakened muscles; (2) chemical changes such as hypercapnia and hypoxemia; and (3) neuromechanical dissociation such as when sensory input from a given inspiratory effort does not match the input anticipated by the brain.[425] The interpretation of this mismatch, or perceived dyspnea, by the cerebral cortex is affected by the individual's expectations, experiences, and beliefs, making the sensation of dyspnea highly subjective and individual.

Diagnosis and Assessment

Neither clinical signs such as respiratory rate or oxygen saturation nor laboratory data such as arterial blood gases and hemoglobin concentration are reliable predictors of dyspnea. Because objective data correlates poorly with dyspnea, the gold standard for measuring and assessing dyspnea is the patient's self-report. The visual analogue scale[427] and Borg scale[428] are among the most widely used in adults. The Borg scale is a 10-point scale with descriptive anchors at the ends. A numeric rating scale has also been evaluated in adult oncology patients, with a 0/1 out of 10 score having a 98% sensitivity and a 54% specificity. A score greater than 1 is predictive of dyspnea that may impair daily function and is recommended as a threshold score requiring further evaluation.[429] The Dalhousie dyspnea scale was developed to meet the need for a pediatric dyspnea assessment instrument.[430] This pictorial instrument actually contains three scales depicting three subconstructs of dyspnea including throat closing, chest tightness, and effort. This instrument was tested in children with asthma or cystic fibrosis and in healthy children. Children 8 years or older used the instrument reliably. Our review of the literature did not yield any instruments that have been specifically developed for the measurement of dyspnea in the younger pediatric population.

Further assessment of dyspnea necessitates a history that should include triggers or exacerbating factors, alleviating factors, severity, and description of degree of functional impairment. Indications of complications such as infection, GVHD, and cardiac compromise should be sought, as should potential treatment-related causes such as chemotherapy and radiotherapy. Potential causes of dyspnea unrelated to malignancy such as asthma should also be considered. Finally, contributing psychosocial factors such as anxiety should be explored because emotional and cognitive factors may influence how the individual interprets dyspnea as a symptom.

Evaluation beyond a thorough physical examination depends upon the suspected cause of dyspnea. Studies that may provide useful information include a complete blood cell count, noninvasive measures including pulse oximetry and capnometry, selective assessment of venous or arterial blood gases, and a chest radiograph. Additional tests that may also be considered include pulmonary function testing, an axial chest CT scan, an echocardiogram, an electrocardiogram, and a spiral CT or ventilation-perfusion scan to assess for a pulmonary embolus.

Management

Targeted approaches to treat dyspnea depend upon the underlying cause and may include medical therapies such as chemotherapy, antibiotics, or diuretics. Procedural interventions may include pleurocentesis and stenting of the airways to relieve the obstruction or surgical removal of the obstruction. Consideration of such interventions should weigh the likely benefits and burdens for the child in light of his or her medical condition.

Rapid and effective strategies for symptomatic management of dyspnea are available and applicable both for patients who are candidates for targeted approaches and for those in whom such interventions are not appropriate. The mainstays of symptomatic management include opioids and oxygen. Other agents such as anxiolytics, steroids, and bronchodilators may also be of benefit, particularly if an inflammatory or bronchospastic component is suspected.

Opioids

Several studies in adult patients with cancer support the use of opioids as an effective intervention for dyspnea.[431-434] Bruera et al.[431] and Mazzocato et al.[433] conducted randomized placebo-controlled crossover studies demonstrating that opioids relieved dyspnea and furthermore did not cause clinically important respiratory depression. No studies demonstrating the efficacy of opioids for dyspnea in children have been published, although based on clinical experience, they appear to be as effective and safe in children as in adults.

The mechanism(s) by which opioids relieve dyspnea has/have not yet been clearly elucidated. Opioid receptors present in both the peripheral nervous system and the CNS may play a role relieving dyspnea when they are bound. Opioids may alleviate dyspnea by blunting the effect of hypercapnia or hypoxia on ventilation, relieving anxiety, or modifying the sensation of dyspnea, akin to their ability to modify the sensation of pain.

The dose required to relieve dyspnea is often relatively small, even when a patient is not opioid-naive. For example, Allard and colleagues[434] showed that a 25% increase in the baseline dose controlled breakthrough dyspnea for up to 4 hours. Our standard practice for opioid-naive patients is to start by administering 0.025 mg/kg of morphine intravenously (i.e., 25% of 0.1 mg/kg, the typical starting dose for pain) and titrating as indicated. In addition to short-acting preparations, long-acting preparations such as sustained-relief morphine are effective treatments for dyspnea.[435]

Because opioid receptors are present in the lower respiratory tract, it was postulated that nebulized opioids might alleviate dyspnea. Case reports of inhaled morphine and fentanyl in adolescents with cystic fibrosis[436,437] and a small uncontrolled study in patients with cancer who used inhaled morphine fentanyl to reduce dyspnea held promise in this regard.[438] A crossover study conducted by Bruera and colleagues[439] comparing subcutaneous and nebulized morphine suggested that both routes of administration may reduce dyspnea, but perhaps because of a small sample size or placebo effect, a difference between the two routes could not be excluded. In addition, several other studies have not demonstrated efficacy of nebulized opioids. Until larger studies are conducted that use standardized doses of opioid and consistent delivery methods, evidence is insufficient to support this method of delivery for dyspnea.[440]

Oxygen

When hypoxemia is suspected to be the cause of dyspnea, administration of oxygen to reverse hypoxemia may relieve this symptom. However, it is likely that most patients who have dyspnea either are not hypoxemic or do not have dyspnea as a result of hypoxemia alone. For example, in a study of adults with advanced cancer and dyspnea, only 40% were hypoxic.[441]

Studies evaluating oxygen compared with air for relief of dyspnea in both hypoxemic and nonhypoxemic adults show no clear superiority of oxygen compared with air.[442-445] An explanation for the comparability of flowing oxygen and air in relieving dyspnea is based on the ability of both to stimulate mechanoreceptors in the trigeminal nerve. Receptors in the distribution of the trigeminal nerve appear to influence induced dyspnea in healthy subjects.[446] In addition, administration of cold air appears to improve dyspnea in patients with chronic obstructive pulmonary disease.[447] Therefore provision of flowing air or oxygen could potentially reduce dyspnea through this mechanism. Trigeminal nerve stimulation may explain why experiencing cool, moving air provided by a fan or open window also seems to reduce dyspnea.

Anxiolytics

Although anxiety may worsen perceived dyspnea and dyspnea may induce anxiety, evidence to date does not support the routine use of anxiolytics to treat dyspnea, particularly not as a first-line agent. Dyspnea is a common symptom in persons who have panic attacks or anxiety disorder. However, anxiety may contribute less to coexisting dyspnea than has been traditionally thought. Recent work reveals that in adults with advanced cancer, anxiety explained only 10% of the variance in dyspnea. Use of an anxiolytic agent to alleviate anxiety may be appropriate when anxious symptoms are particularly prominent and are thought to have a significant influence on a patient's interpretation of the sensation of dyspnea. Anxiolytics may also be indicated for sedation to manage escalating dyspnea at the end of life, as discussed in Chapter 69, which covers palliative care.

Nonpharmacologic Interventions

To the extent that the cerebral cortex mediates the sensation of dyspnea, interventions that modify cognitive and emotional factors such as breathing/relaxation training that influence the interpretation of dyspnea may be helpful. In healthy adults undergoing induced dyspnea, distraction of subjects did not change dyspnea severity ratings but did decrease the perceived unpleasantness of the dyspnea.[448] Increased support, such as is provided in the nurse-run dyspnea clinic studied by Bredin and the one described by Booth, may reduce dyspnea by providing education, cognitive and behavioral training, and psychosocial support.[449]

Escalating Dyspnea

The symptom of dyspnea may escalate at the end of life. Respiratory changes and the development of secretions are discussed in Chapter 69, which covers palliative care. Refractory, distressing dyspnea such as may occur at the end of life is an indication for consideration of palliative sedation, as described in Chapter 70.

Future Directions

Much remains to be learned regarding the physiologic features and mechanisms of dyspnea. Once these features and mechanisms are better understood, targeted interventions may be developed to ameliorate this challenging symptom for which we currently have relatively few treatment options. Within the pediatric realm, a better understanding of how children sense and interpret this highly subjective symptom is needed. This understanding in turn may enable development of methods to measure and assess this symptom, allowing the care team to better understand how it affects children and evaluate dyspnea-directed interventions.

COUGH

Cough can be a distressing symptom and may lead to dyspnea, vomiting, sleep disruption, and chest or throat pain. Topical antitussives act on receptors in the respiratory tree to reduce cough. Nebulized lidocaine has been described to ease an intractable cough at the end of life.[450] Symptomatic treatment for a significant cough usually entails administration of an opioid to suppress the cough reflex in the medulla. Dextromethorphan and codeine are most commonly used, although all opioids have antitussive activity.

FATIGUE

Cancer-related fatigue has been defined by the NCCN as a "distressing persistent, subjective sense of tiredness or exhaustion related to cancer or cancer treatment that is not proportional to recent activity and interferes with usual functioning."[451] Fatigue is a complex symptom that may have physical, cognitive, and emotional components. In addition, fatigue is subjective and highly individual, and thus patients may experience and interpret fatigue differently. Patients may describe fatigue in a wide variety of ways (Box 73-3). Nevertheless, adults with cancer-related fatigue almost universally report that (1) it is unresponsive to rest, (2) it is not proportional to activity, and (3) it pervades multiple areas of their life. Clearly, this type of fatigue is not the fatigue of everyday life. Recent work in adult cancer survivors reveals that fatigue may be long-lived, lasting for months to years after cancer-directed treatment has been completed.[452,453] In pediatric cancer survivors, fatigue is the only factor associated with both poor physical and psychosocial health-related quality of life.[454]

Impact

It is well established that fatigue is the most common symptom in patients with cancer.[455,456] One survey of published studies on cancer-related fatigue in adults found that fatigue was present in 50% to 75% of patients at diagnosis, with the prevalence increasing to 80% to 96% in patients undergoing chemotherapy and to 60% to 93% in patients receiving radiotherapy.[457] In children, fatigue is less well studied but has been shown to be the most common symptom.[5] For example, Wolfe and colleagues[5] found that fatigue was the most common symptom in children with advanced cancer, with 96% of children experiencing fatigue. Collins also found that in a cross-sectional study of children aged 10 to 18 years who had current or previous cancer, lack of energy was the most common symptom, affecting 49.7%.

According to adult patients with cancer, fatigue is the most distressing of all the symptoms they experience, creating profound physical, psychological, and financial burdens that can impair quality of life and diminish hope.[458] It not only leads to a decrement in physical ability but also to a sense of loss of control, loneliness, and isolation. In the Fatigue II study of 379 adults undergoing treatment for cancer, 60% ranked fatigue as the symptom affecting their life the most.[458] According to the parents in the study by Wolfe et al.,[5] fatigue caused "a great deal" or "a lot" of suffering in 57% of children approaching the end of life. In another study, Jalmsell et al.[6] reported that of 449 parents of children who had died from cancer, 86% reported that fatigue significantly affected their child's well-being. Adolescents who have cancer also report that fatigue significantly affects their physical, social, and psychological well-being.[459] Higher self-reported fatigue in adolescents is also negatively associated with quality of life.[460]

In addition to causing suffering, concerns regarding fatigue as an adverse effect of disease-directed or symptom-directed treatment may limit therapy. Fatigue is documented to be the most common adverse effect of chemotherapy and radiotherapy in adults.[457,461] In adults, treatment-related fatigue can be severe enough to prevent maximal treatment and disease control,[451,462] although in children, fatigue is rarely cited as a reason to reduce therapy. In terms of symptom-related treatment, pain may be inadequately relieved when concerns regarding opioid-related fatigue or sedation inhibit optimal opioid administration.[463,464] When fatigue is not controlled, patients are forced to choose between adequate analgesia with somnolence and mental clouding and less sedation at the price of increased pain.

Approach

Despite its prevalence and impact, fatigue frequently is not addressed by clinicians and patients alike. In a large multicenter study of 1317 adults with cancer, only 52% of those with fatigue reported it to their physician.[465] One significant barrier to addressing fatigue is the perception on the part of the care team that fatigue, although undesirable, does not have a significant adverse affect on patients. In the Fatigue I study it was found that although oncologists believe that pain adversely affects their patients to a greater degree than fatigue (61% vs. 37%), patients with cancer believed that fatigue adversely affected their daily lives more than pain (61% vs. 19%).[456] This disparity may be due in part to clinicians' personal understanding of day-to-day fatigue that leads them to believe they understand the reality of cancer-related fatigue. Other barriers to addressing fatigue may include (1) a belief that fatigue is "normal" or "to be expected" in a patient with cancer; (2) a paucity of descriptors for patients to adequately convey the various manifestations of fatigue; (3) the clinician's lack of familiarity with options to ameliorate fatigue; (4) a disease-directed focus to the exclusion of attention to symptoms; and (5) system-related problems such as time pressures or reimbursement difficulties.

Measurement and Assessment of Fatigue in Children

The NCCN provides guidelines for fatigue management in adults and children that calls for screening for fatigue at every visit using a 1 to 10 scale.[451] Although use of such a scale has not been validated in children, this type of scale may generally be used reliably in children 7 years and older.

Once screening identifies fatigue, it should be further assessed, although universally accepted means for assessing fatigue in either adults or children do not exist. Several unidimensional and multidimensional scales for assessment in adults and a few pediatric instruments are available. One, developed by Hockenberry and colleagues[466] is for children with cancer. Although it is part of a series of instruments that evaluate fatigue in pediatric oncology patients from the perspective of the child, parent, and staff,[466] it was derived from interviews with only 13 children and has not yet been prospectively evaluated. Another instrument, the PedsQL Multidimensional Fatigue Scale,[467] measures child and parent perceptions of fatigue in pediatric patients. This instrument has been studied in healthy children and in children with cancer.[467]

Even when a formal assessment instrument is not used to assess fatigue, clinicians should explore a variety of possible manifestations of fatigue that the child/adolescent and the adult caregiver may identify (Box 71-3). Exacerbating and alleviating factors, the pattern of fatigue, and the degree to which the symptom is affecting the child's life can then be explored. In assessing fatigue it may be helpful to bear in mind that children tend to conceptualize fatigue as a physical sensation, whereas adolescents alternate or merge the physical concept with mental

tiredness.[468] On the other hand, parents and staff conceptualize fatigue as a symptom that interferes with the child's ability to participate in a variety of activities and may be manifested by physical, emotional, and mental changes. Investing the time to fully assess a report of fatigue may frequently yield important clues regarding the cause of the fatigue; these clues are valuable because few diagnostics tests exist to determine the cause of fatigue.

Associated Factors

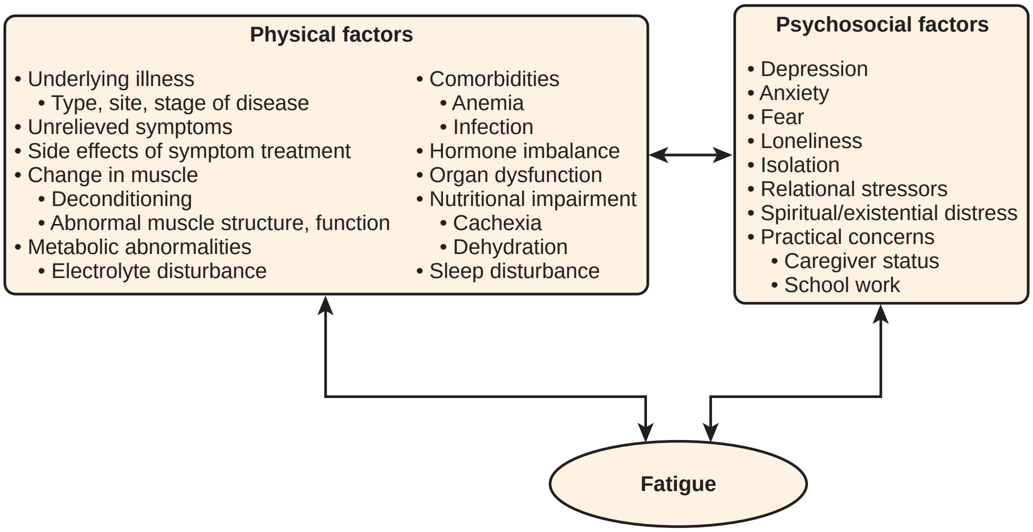
Fatigue may stem from concomitant, interrelated causes including physical factors, psychological factors, and disrupted sleep (Fig. 71-5). Investigations aiming to uncover the cause of fatigue exist only in adults and consist of retrospective and prospective analyses of factors associated with fatigue. No studies have been published that evaluate objective factors associated with fatigue in children with cancer.

For simplicity, factors considered to be associated with fatigue may be categorized into physical and psychosocial factors, with the realization that many patients experience fatigue as a result of a combination of factors. For example, in adults undergoing chemotherapy or radiotherapy, fatigue correlates with both physical factors (symptom distress) and psychological factors (e.g., depression, anxiety, anger, or confusion).[469] Another study of adult patients with cancer similarly determined that both physical factors (severity of pain and dyspnea) and psychological symptoms (anxiety and depression) were associated with the experience of fatigue.[455]

In adults, certain sociodemographic factors are also associated with fatigue. For example, the demographic factors of being employed or living alone were significantly associated with the symptom of fatigue.[470] Although children are unlikely to experience fatigue related to these exact sociodemographic considerations, the stress induced by these financial or caregiver concerns can affect children and the fatigue that they experience.

Physical Factors

Physical factors contributing to fatigue include direct effects of the underlying disease and adverse effects of treatment of the underlying illness. Unrelieved symptoms are also likely to contribute to a patient's fatigue. In adults, overall symptom distress is associated with the report of fatigue.[471] Conversely, treatment for symptoms such as pain or dyspnea may also contribute to fatigue.



Physical factors
• Underlying illness
• Type, site, stage of disease
• Unrelieved symptoms
• Side effects of symptom treatment
• Change in muscle
• Deconditioning
• Abnormal muscle structure, function
• Metabolic abnormalities
• Electrolyte disturbance
• Comorbidities
• Anemia
• Infection
• Hormone imbalance
• Organ dysfunction
• Nutritional impairment
• Cachexia
• Dehydration
• Sleep disturbance
Psychosocial factors
• Depression
• Anxiety
• Fear
• Loneliness
• Isolation
• Relational stressors
• Spiritual/existential distress
• Practical concerns
• Caregiver status
• School work
Fatigue

Figure 71-5 A conceptual model of fatigue.

Because a variety of medications including benzodiazepines, opioids, and antihistamines may cause fatigue, thoroughly reviewing the patient's medications may reveal medications that cause fatigue. Finally, a variety of comorbidities such as organ dysfunction (e.g., renal, hepatic, cardiac, pulmonary, or endocrine dysfunction), electrolyte imbalance, poor nutritional status, and infection may contribute to fatigue.

Anemia is a well-established cause of fatigue in a variety of patient populations. In adults with cancer, it has been demonstrated to be associated with fatigue and impaired quality of life. In some adults with advanced cancer, anemia is not significantly related to fatigue.[472,473] Thus anemia may not fully account for the fatigue experienced by some patients, suggesting that correction of anemia may or may not decrease fatigue.

Like anemia, hypothyroidism is associated with fatigue in patients with and without cancer. Other endocrine abnormalities that are associated with the experience of fatigue include hypothalamic-pituitary axis alterations[474] and hypogonadism, which is also associated with negative mood and cachexia.[475-477]

Deconditioning from decreased activity may lead to fatigue, which in turn lessens activity and may further exacerbate fatigue. A variety of muscle abnormalities that have been described in patients with cancer may be associated with fatigue.[478] Finally, muscle wasting (cachexia) is associated with fatigue, perhaps because of the cytokines proposed to mediate cachexia such as tumor necrosis factor, which are also thought to contribute to the sensation of fatigue.[474]

Psychosocial Factors

Psychosocial factors such as depression and anxiety, existential or spiritual suffering, and stress from practical concerns may all be related to fatigue. When psychological factors such as fatigue and depression coexist, depressed mood may be a contributor or a consequence of fatigue. For example, when characterized by withdrawal and decreased participation in activities in an adolescent, fatigue may be a manifestation of depression. On the other hand, the experience of fatigue may lead to isolation, decreased engagement in activities, and impaired quality of life, all of which may contribute to depression.

Sleep Disturbance

Sleep disturbance, manifested as decreased quantity or quality of sleep, results from factors including unrelieved physical or psychological symptoms or environmental factors, such as distortion of sleep architecture by medications or sleep disruptions that occur in the hospital.[479,480] Impaired sleep may in turn worsen the physical or psychological distress experienced by patients. Although a decrement in the quantity or quality of sleep may contribute to fatigue, cancer-related fatigue may occur independent of changes in sleep.[481]

Interventions

An algorithm for approaching the symptom of fatigue is presented in Figure 71-6. Although fatigue is frequently multifactorial, targeting underlying factors that are suspected to contribute to fatigue can improve this symptom. Even when no particular contributing factor is identified, nonspecific interventions may ameliorate fatigue. For example, exercise and stimulants are effective interventions that reduce fatigue. Educating the patient and his or her family about fatigue is important in helping them understand fatigue and its impact, as well as the available options for addressing it. Strategies to optimize function and facilitate adaptation to fatigue such as realistic goal setting, modifying activities, and conserving energy should also be reviewed.

Exercise

Curtailing activity is a natural reaction to fatigue, and oncologists report recommending activity in response to the complaint of fatigue.[456] Several randomized controlled trials in adults have demonstrated that exercise actually reduces fatigue, and in some instances it also ameliorates psychological symptoms such as depression and anxiety. For example, a 6-week walking program for women undergoing radiotherapy for breast cancer improved fatigue as well as anxiety, depression, and sleep disturbance.[482] Finally, exercise can also provide a variety of physical benefits, including improved strength and function.

Psychosocial Interventions

Strategies to address psychological factors include both pharmacologic and nonpharmacologic approaches. Psychological interventions such as psychotherapy and support group participation may reduce fatigue,[483] as can increased support from clinicians such as intensive nursing support.[484] If depression or anxiety are suspected to contribute to fatigue, a trial of a pharmacologic agent such as an antidepressant or anxiolytic may be of benefit, recognizing that some drugs in each of these classes may exacerbate sedation and fatigue. If other stressors are uncovered, such as spiritual suffering or concerns about practical matters, professionals such as a chaplain, resource specialist, or staff at school should be approached for assistance.

Sleep

If sleep disturbance is suspected, reducing factors that impair sleep and strategizing with patients to improve sleep hygiene are a necessary first step. If indicated by persistent or severe sleep impairment, pharmacologic interventions such as benzodiazepines, benzodiazepine receptor agonists, and antidepressants with sedating qualities (e.g., TCAs, trazodone, and mirtazapine) may be tried. It is important to keep in mind, however, that benzodiazepines and antihistamines in particular may have paradoxic effects in children and that the benzodiazepine receptor agonists have not yet been well studied in young children.

Pharmacologic Interventions

Correction of Anemia. Correcting anemia associated with cancer or chemotherapy with erythropoietin is a strategy often used in adult oncology. Some studies support this practice in adults, demonstrating that

improving anemia may also improve fatigue-related quality of life.[485] However, correction of anemia with erythropoietin has not been as widely pursued in pediatric oncology practice, in part because no evidence exists that treatment of anemia with erythropoietin improves quality of life. The one published study examining this question in children failed to show that health-related quality of life improved with correction of anemia.[486] The authors provide several possible explanations for this finding, but the lack of association between correction of anemia and quality of life and fatigue suggests that focusing on anemia at the exclusion of other suspected causes of fatigue and decreased quality of life may lead to inadequate treatment of fatigue. If erythropoietin is used, recent concerns that it is associated with more rapid tumor progression, thrombosis, and increased mortality in adults[487-489] should be kept in mind. If anemia is suspected as a cause of fatigue, transfusion support is an alternative to erythropoietin therapy.

Stimulants. The stimulant with the best-established efficacy in ameliorating fatigue in adults who have serious illness is methylphenidate. This agent reduces fatigue in adults with cancer and human immunodeficiency virus, regardless of the underlying cause.[490,491] In one study of adults with cancer-related fatigue, patients had significantly less fatigue after they started taking methylphenidate.[492] However, studies have not consistently demonstrated the efficacy of methylphenidate in reducing fatigue. These discrepancies are likely due to the variation in dosing and titration procedures, as well as heterogeneity in fatigue assessment instruments and the study populations evaluated. Methylphenidate is advantageous in that it improves cognition and exerts direct analgesic and antidepressant actions,[490,492,493] and one study reports success in improving cognition in children who have survived cancer.[494] A case series documenting successful treatment with methylphenidate of opioid-related sedation in children who have cancer has been published,[495] but currently no randomized controlled trials have been published that evaluate its efficacy or tolerability in children with cancer-related fatigue.

Methylphenidate has a history of extensive use in children with attention deficit hyperactivity disorder[496] and has a well-established track record in terms of being safe and well tolerated by children. The most prevalent adverse effect of methylphenidate is decreased appetite, which we attempt to mitigate by giving the first dose after breakfast. Despite concerns that methylphenidate should be used with caution in children at risk for seizure, open-label and controlled trials in adults and children with attention deficit hyperactivity disorder and epilepsy do not support this concern (reviewed by Baptista-Neto et al.[497] in 2008). For example, a recent study in children with epilepsy found no increase in seizure frequency and in fact observed beneficial electroencephalogram changes with methylphenidate.[498] Modafinil may be considered as an alternative to methylphenidate, although significantly less pediatric experience exists with this agent. Modafinil has been used with success to treat children with narcolepsy[499] and excessive daytime sleepiness associated with Prader-Willi syndrome[500] and to treat adults with fatigue associated with multiple sclerosis or sedation due to opioids.[501,502] However, no studies evaluating its use in children to treat cancer-related fatigue have been published.

Integrative Therapies

Adult patients with fatigue are more likely to use dietary and herbal supplements,[503] which may be related to patients' perceptions that conventional medicine offers no effective interventions for fatigue. Patients reporting fatigue should be questioned regarding potential use of dietary and herbal supplements. A randomized controlled study evaluating ginseng in adults found that subjects who received 1000 mg per day for 8 weeks had significantly improved fatigue scores when compared with subjects who received a placebo.[504]

Future Directions

Despite its prevalence and impact, fatigue is frequently underrecognized and underappreciated, particularly in comparison with other symptoms. Particular areas of need in the management of fatigue include a better developed assessment method, increased understanding of causes of fatigue, and interventions targeted at specific causes of fatigue.

PRURITUS

Pruritus, also referred to as itching, may occur in children who have cancer for a variety of reasons. As a paraneoplastic symptom it may be associated with malignancy, such as Hodgkin lymphoma or other types of lymphoma. Other disorders such as mastocytosis, iron deficiency, and polycythemia vera may cause pruritus. Pruritus may also occur with organ dysfunction such as hypothyroidism, hyperparathyroidism, liver dysfunction (i.e., cholestasis) or renal dysfunction (uremia),[505] as well as infection of the skin. Pruritus may also be iatrogenic and occur as a result of cancer-directed therapy, as in the pruritic rash caused by growth factor receptor inhibitors[506]—for example, in skin GVHD after hematopoietic stem cell transplantation. Pruritus may also result from a variety of other medications, as well as blood products. Rarely, pruritus may be a manifestation of an underlying psychiatric or neurologic disorder. In general, pruritus associated with a systemic disease is generalized, more gradual in onset, and accompanied by normal appearing skin.[505]

Although pain and pruritus are distinct sensations, they are mediated by the same neural pathways. Stimulation of unmyelinated C fibers that are situated in the dermal-epidermal junction (which are more superficial than those responsible for detecting pain) creates impulses that travel to the dorsal root ganglia and cross to the contralateral spinothalamic tract and ultimately to the somatosensory cortex. Neurotransmitters thought to mediate the sensation of pruritus include the amines, histamine and serotonin, opioids, eicosanoids, neuropeptides, and cytokines. Histamine, which is released primarily in the skin from mast cells, mediates pruritus via H1 and H2 receptors. The superficial C fibers are especially sensitive to histamine release. By binding to 5-HT3 receptors on C fibers, serotonin also plays a role in inducing pruritus. Finally, endogenous opioids also appear to affect itching, potentially through both central and peripheral mechanisms.

Pruritus triggers the urge to scratch through a spinal reflex, and scratching transiently relieves pruritus. However, persistent scratching can worsen pruritus and lead to more serious consequences, such as skin breakdown and infection. Pruritus is likely worsened by a variety of factors including dry skin, pain, boredom, or anxiety. Conversely, distraction and competing stimulation of the skin such as by painful stimuli may reduce this symptom.

Opioid-induced pruritus is a common problem in patients treated with systemic opioids. For example, Maxwell and colleagues[382] found that as many as 77% of children who received IV morphine by PCA experienced pruritus. The incidence of pruritus with use of opioids administered via the spine is also high, occurring in 20% to 90% of patients, particularly in the postoperative setting. The incidence of itching with spinal opioids appears lower in opioid-tolerant patients who have advanced cancer.[507] Whereas the itching associated with systemic opioids is usually widespread, the itching observed with spinal opioids tends to be more segmental.[505]

Although opioids do cause histamine release from mast cells, this phenomenon does not seem to account for most of the pruritus attributed to opioids, for several reasons. First, fentanyl does not cause histamine release, but it may still cause pruritus.[507] Second, opioids administered via the spine (e.g., morphine in doses up to fiftyfold lower than those used systemically) can produce intense and prolonged itching despite evoking negligible peripheral histamine release. Third, as will be detailed later, antihistamines are much less effective for opioid-induced itching compared with interventions that influence opioid-receptor coupling to G-protein–mediated intracellular actions. Possible explanations for opioid-induced pruritus include central activation of itch centers, activation of serotonergic pathways, and opioid-receptor–mediated activation of G-stimulatory proteins.

Interventions

Effective control of pruritus is important to provide comfort, improve quality of life, and prevent potential worsening of any underlying dermatologic condition or complications, such as infection. Treatment should be targeted to the suspected underlying cause, if possible. For example, the most effective treatment for pruritus resulting from Hodgkin lymphoma is cancer-directed therapy. Similarly, stenting of the bile duct, if clinically appropriate, is the most effective treatment for cholestatic pruritus. Depending on the degree and extent of involvement, pruritic GVHD may be treated with systemic immunosuppression, topical steroids, or topical tacrolimus.[508] Pruritus from histamine-mediated reactions (e.g., allergic reactions) often responds to antihistamines such as diphenhydramine. These agents should not be used indiscriminately or without regard for the underlying cause because they may contribute to mental status changes such as sedation, confusion, and delirium.

Antihistamines are typically ineffective in persons with cholestatic or uremic pruritus. Cholestyramine is effective in reducing pruritus associated with cholestasis, presumably by binding bile salts or other accumulated pruritogens. Randomized placebo-controlled trials have shown that cholestatic pruritus is relieved by naloxone or its oral equivalent, naltrexone, perhaps through opioid receptors thought be activated in this clinical condition.[509-511] Ondansetron may also reduce itch from cholestasis.[512-514] Cholestatic pruritus has also been reported to respond to midazolam in the absence of sedation, with the effect purportedly achieved through increased γ-aminobutyric activity.[515] For uremic pruritus, studies have yielded conflicting results for both the efficacy of ondansetron[516,517] and naltrexone.[518,519] Uremic and postburn pruritus, both considered forms of neuropathic itch, are relieved with use of either gabapentin or pregabalin.[520,521]

Biologic cancer treatments, such as epidermal growth factor receptor inhibitors, commonly cause pruritus. A single published study supports the use of aprepitant (125 mg on day 1 and 80 mg daily on days 2 and 3) for pruritus associated with erlotinib.[2] It is hypothesized that neuropeptide substance P activates mast cells in the lesional skin of persons who are treated with erlotinib, and because it is an NK-1 receptor antagonist, aprepitant may ameliorate itch.[522]

Interventions for Opioid-Associated Pruritus

Despite the widespread use of antihistamines for treatment of opioid-induced pruritus, data on their effectiveness in this setting are remarkably sparse, and some randomized controlled trials indicate lack of effectiveness.[523] One study found that hydroxyzine was superior to placebo in a postoperative setting, but most other trials have shown no differences between antihistamines and placebo.[523] Similarly, we have been unable to identify any trials showing effectiveness of the less-sedating antihistamines, such as cetirizine, fexofenadine, or loratadine, for opioid-induced itching.

Several studies, including a prospective, randomized controlled trial in children and adolescents receiving postoperative analgesia with a morphine PCA, have shown that low-dose naloxone infusions (0.25 μg/kg/h) reduce opioid-induced pruritus, and to a lesser extent nausea, without increasing opioid requirements or pain scores.[381,382,524] More recently, a prospective dose-finding study found a higher naloxone dose (1 μg/kg/h) to be more consistently effective in preventing opioid-induced adverse effects.[383] When low-dose naloxone infusions and nalbuphine are used to treat itching in patients who are quite opioid-tolerant, some uncertainty exists regarding whether to begin with lower or higher infusion rates or doses, but the 1 μg/kg/h rate appears to be appropriate for this population as well.

Systemic opioid-induced pruritus may be addressed by opioid rotation.[525] In one study of 90 children receiving morphine, hydromorphone, or fentanyl for postoperative pain, it was found that pruritus was more severe in the morphine group.[526] To our knowledge, however, no other studies have demonstrated superiority of one opioid over another in terms of pruritus.

Low-dose systemic infusions of opioid antagonists are widely used for patients receiving opioids administered via epidural and spinal routes. Nalbuphine is a mixed-agonist antagonist that is widely used to treat itching (as well as nausea and other adverse effects) from systemic and neuraxial opioids. A common dosing schedule is 0.01 to 0.02 mg/kg IV every 6 hours, to a maximum total dose of 1.5 mg. Note that these doses are fivefold to tenfold lower than the starting doses recommended when nalbuphine is administered as an analgesic.

Ondansetron has been shown to reduce systemic opioid-associated scratching, although the reduction in opioid-induced itching was not statistically significant.[527] Ondansetron reduces pruritus from intrathecal morphine,[528-530] although the mixed opioid agonist nalbuphine may be superior to ondansetron for this purpose.[531]

Our clinical impression, unconfirmed by data, is that pruritus is a more significant problem in the initial weeks of opioid use and that for many patients with advanced cancer who are receiving escalating doses of opioids, pruritus becomes less problematic as opioid tolerance progresses.

Topical Approaches

Any potential skin irritants such as perfumed skin products and harsh detergents should be avoided. When dry skin is thought to compound itching, application of a moisturizer may be helpful. Medicated baths containing oatmeal or baking soda, as well as the application of ice or cold compresses, may quell the itching sensation. Topical agents such as capsaicin (0.025% cream) or Sarna lotion containing camphor and menthol may also soothe skin. Successful use of topical naltrexone to relieve pruritus in persons with atopic dermatitis has recently been reported, suggesting that opioid receptors are involved in a variety of pruritic conditions, although this strategy remains experimental at this point.[532]

Other Potential Therapies for Pruritus

Several antidepressants have been used to treat pruritus. In adult dermatology practice, TCAs, especially doxepin, are widely used. TCAs appear to reduce itch and pain due to postherpetic neuralgia. Paroxetine has been implicated in providing relief from pruritus in a variety of situations, including paraneoplastic itch, opioid-induced itch, and pruritus associated with polycythemia vera. In a small randomized controlled trial of 26 patients with pruritus from a variety of nondermatologic causes, Zylicz[532a] found that one third of patients experienced a modest improvement in pruritus with paroxetine, although it was not reported which patients benefited. In addition, some patients received concurrent cisapride, a 5-HT3 receptor antagonist, which could have accounted for the improvement in pruritus through serotonergic mechanisms.[533] The antidepressant mirtazapine, which has 5-HT2, 5-HT3, H1 antagonist, and noradrenergic activity, was reported to ameliorate pruritus in a case series of four patients with either cholestatic, uremic, or paraneoplastic pruritus. It is unclear whether it is serotonergic blockage at the peripheral or central level that reduces pruritus or whether sedation per se contributed to its efficacy. Other medications used for neuropathic pain, such as anticonvulsants and systemic local anesthetics, have also occasionally been used for patients with refractory pruritus.

MOOD DISORDERS AND MENTAL STATUS CHANGES

Depression

Children with cancer may experience depression that predates their cancer diagnosis or develops after their cancer diagnosis. The reported prevalence of depression in children with cancer varies, likely because of differences in assessment techniques and the populations studied. In general, it does not appear that children with cancer have more psychological symptoms, including depression, than do other children.[534-536] For example, Noll and colleagues[535] found no significant differences in measures of depression, anxiety, or loneliness between children with cancer and their classroom peers. Psychologists have proposed that the similarity in depression diagnosis rates is due to use of avoidant or repressive styles of coping with the cancer experience.[537,538]

Physical symptoms stemming from cancer or its treatment can also occur in people with depression and in fact may be diagnostic criteria for depression. Adults diagnosed with major depression have been shown to have higher rates of such nonspecific symptoms, including fatigue, decreased appetite, and sleep disturbance.[539] Standardized screening measures for healthy children have not been validated in the pediatric oncology population. Clinicians may find it helpful to rely on psychological symptoms such as guilt, hopelessness, worthlessness, or anhedonia to make the diagnosis of depression. However, clinicians have been demonstrated to underestimate psychosocial symptoms such as depression and anxiety in children with cancer.[540]

Risk factors for the development of depression in children with cancer include perceived stress, lack of social support, not receiving open information about their diagnosis and prognosis at the initial stage of the disease, and parental anxiety.[537,541,542] Cancer survivors are also at risk for depression.[543,544] For example, adolescents who had cancer as children are 1.5 times more likely to have depression or anxiety[544] and are at higher risk for suicidal ideation than are their siblings.[545] Depression in this case may be due to impaired social functioning as a result of cancer or its treatment.[543]

Oncologists play a crucial role in screening patients for psychological disorders and for implementing first-line treatments for depression and anxiety (described later). Involvement of a psychosocial team is crucial. Most oncologists prescribe selective serotonin reuptake inhibitors (SSRIs), although some only do so in conjunction with a mental health consultation for the child.[546] Options for medical interventions for depression include TCAs, SSRIs, and newer selective serotonin norepinephrine reuptake inhibitors. TCAs are rarely used for depression because of their anticholinergic adverse effects and the lack of efficacy data in children. SSRIs appear to be the most commonly prescribed class of antidepressants in children with cancer.[547,548]

No particular antidepressant has been demonstrated to be superior to another in the pediatric cancer population. Instead, the choice of antidepressant should be determined by the characteristics, including adverse effect profiles, of different agents. For example, mirtazapine may be an optimal agent for a child with anorexia or difficulty sleeping. Likewise, a TCA may be the treatment of choice for a child with concomitant neuropathic pain. A modest increase in suicidal ideation has been noted in studies evaluating children treated with SSRIs compared with placebo.[549] The FDA now requires labeling of all antidepressants to warn clinicians of such a risk.[550] Although the meaning of the increased risk is unclear, initiation of an antidepressant warrants discussion of the risks and benefits with families and close monitoring of children for worsening depression or signs of suicidality. Some medications such as tramadol, triptans, and linezolid interact with SSRIs, increasing the risk of serotonin syndrome. Children with depression who do not respond to these measures, and children with suicidal ideation or complex psychological symptoms, should be referred for formal psychiatric evaluation.

Evaluation of screening for depression, longitudinal studies of mood disorders and their predictors, and prospective evaluation of interventions for children with cancer and depressive symptoms are clearly needed to better understand and ameliorate depression in children with cancer.

Anxiety

Children with cancer may experience anxiety that is situation-dependent (e.g., related to treatment). Such anxiety may respond to anxiolytic medications administered prior to treatment, as well as cognitive or behavioral interventions. Such nonpharmacologic interventions are described in more detail in the section on pain. Other types of anxiety in children should be approached with an exploration of potentially contributing factors (e.g., stress related to family or school) and referral for increased psychosocial support. A child with anxiety who meets the criteria for a psychiatric anxiety disorder (e.g., generalized anxiety disorder and panic disorder) or a child whose anxiety significantly impairs his or her function should be referred for psychiatric evaluation.

Delirium

Delirium is a state of disturbed consciousness or level of arousal characterized by an inability to focus or to maintain or divert attention. Delirium has a rapid onset and results in significant confusion for the patient. Delirious patients may have mumbling speech, perceptual disturbances with delusion or hallucinations, or alterations in their sleep/wake cycle. Patients may exhibit hyperalert-hyperactive delirium with anxiety, agitation, or even aggression. Alternatively, patients may have hypoalert-hypoactive delirium, characterized by slowed reactions and difficulty focusing. Delirium is a disturbing symptom for patients and may be extremely distressing for caregivers.[551]

Delirium may be caused by metabolic disturbances (e.g., hypoglycemia or electrolyte abnormalities), CNS pathology, liver or kidney dysfunction, infection, constipation, or urinary obstruction. The most common cause of delirium is a drug effect. The most common offending medications are anticholinergics, corticosteroids, benzodiazepines, and opioids. For this reason, delirium should never be treated with escalation of opioid therapy unless uncontrolled pain is suspected. Instead, the opioid dose should be decreased if possible or converted to an alternative opioid. In addition, psychoactive medications should be discontinued, if possible, and a neuroleptic such as haloperidol should be inititated. In fact, a randomized controlled trial of haloperidol versus chlorpromazine or lorazepam for adults with human immunodeficiency virus and delirium was halted early because of adverse effects in the lorazepam arm. Haloperidol should be initiated by dose escalation similar to the process used for treating pain.

Atypical antipsychotic medications have also been used successfully in adults with delirium, although no trials comparing them with haloperidol have been performed.[552] For delirium with significant agitation, benzodiazepines may be considered, but they may cause paradoxic exacerbation of symptoms. Regardless of the pharmacologic agent used, concomitant nonpharmacologic interventions should always be used as well. Measures to reduce stimulation in the environment or to orient the patient, such as a familiar person remaining with the patient and frequent orientation to time and place, may be helpful.

Corticosteroid-Induced Mood and Behavior Disturbance

Psychiatric abnormalities including depression, mania, hypomania, and psychosis, as well as cognitive changes due to corticosteroid therapy, are well described. Among children with ALL, both dexamethasone and prednisone are associated with neurobehavioral adverse effects, and preschool-aged children appear to be at greater risk for these effects.[553] Such alterations are reversible with dose reduction or discontinuation of treatment. However, dose reduction or discontinuation of corticosteroids administered for antineoplastic purposes, as in therapy for ALL, may not be possible. Reports of successful use of olanzapine or promethazine for steroid-associated psychosis or mood disturbance have been published. Risperidone also appears to be an effective short-term pharmacologic agent for corticosteroid-related mood disturbance or psychosis related to corticosteroid treatment for ALL.[554]

   Using self-report data from 164 children and adolescents with progressive cancer, the investigators report symptoms experienced by children and adolescents with cancer. Symptoms included some that are often unrecognized, including anorexia, weight loss, and weakness. The prevalence and nature of symptoms experienced varied between cancer types.

    This article presents findings from the Adolescent and Young Adult Health Outcomes and Patient Experience (AYA HOPE) study, involving a cohort of 523 AYA patients with cancer. AYAs had significant decrements in physical and mental health–related quality of life domains and experienced higher levels of fatigue.

55. Michelet D, Andreu-Gallien J, Bensalah T, et al: A meta-analysis of the use of nonsteroidal antiinflammatory drugs for pediatric postoperative pain. *Anesth Analg* 114(2):393–406, 2012.

    This meta-analysis provides definitive evidence that perioperative nonsteroidal antiinflammatory drugs reduce opioid consumption and result in less postoperative nausea and vomiting. Although *the study is based in the postoperative setting, clinicians in other scenarios in which nonsteroidal antiinflammatory drugs are a viable option should consider their use, given their opioid-sparing effect.*

This randomized controlled trial demonstrated that infants undergoing major surgery who received intermittent intravenous paracetamol required less morphine for analgesia than did those in the placebo group, providing evidence that paracetamol may also be opioid-sparing.

62. Collins JJ, Grier HE, Kinney HC, et al: Control of severe pain in children with terminal malignancy. *J Pediatr* 126(4):653–657, 1995.

In this retrospective medical record review it was found that standard dosing of opioids controls cancer-related pain in most children, although a group requiring massive opioid infusions exists and is associated with solid tumors metastatic to the spine and major nerves.

69. Williams DG, Patel A, Howard RF: Pharmacogenetics of codeine metabolism in an urban population of children and its implications for analgesic reliability. *Br J Anaesth* 89(6):839–845, 2002.

This United Kingdom–based study demonstrated that reduced ability to metabolize codeine to morphine (due to genetic variation in the cytochrome P450 enzyme CYP2D6) is relatively common. This finding suggests that codeine may provide unreliable analgesia for a significant number of children.

70. Clark E, Plint AC, Correll R, et al: A randomized, controlled trial of acetaminophen, ibuprofen, and codeine for acute pain relief in children with musculoskeletal trauma. *Pediatrics* 119(3):460–467, 2007.

In this randomized, controlled trial comparing acetaminophen, ibuprofen, and codeine for relief of pain in children with musculoskeletal injury, ibuprofen provided a significant decrease in pain score, and neither codeine nor acetaminophen provided adequate analgesia.
